When using the Peach–Koehler formula, it is immaterial whether σ_{ij}^e is an externally imposed stress field or the stress arising from another internal source of stresses. Thus, if σ_{ij}^e is identified with the stress associated with another dislocation, this formula determines the force between the two dislocations. The interaction energy between two dislocations marked, respectively (1) and (2), separated by a distance r , can then be evaluated as the work done when the dislocation (2) is brought in from a distance R , against the force $F^{(1-2)}$ exerted on dislocation (2) by the dislocation (1). This force obviously decreases as $1/r$. The interaction energy per unit length of the dislocations is then $E_{(1-2)}^{\text{int}} = -\int_R^r F^{(1-2)} dr$. This interaction energy, proportional to $\ln(R/r)$, could also be evaluated as the part of the elastic energy corresponding to the cross terms between the stress and strain fields of dislocations (1) and (2), respectively. Similarly, elastic interaction between dislocations and other defects inducing internal stresses, such as inclusions, cracks, stress inducing point defects, is determined.

Dislocation Multiplication

Consider first the homogeneous nucleation of a circular glissile dislocation loop. The energy of such loop as a function of its radius is given above. The work done by the shear stress σ parallel to the Burgers vector acting in the plane of the loop during the growth of the loop is $\sigma b \pi r^2$. If the loop is to form and grow spontaneously, this work has to exceed its elastic energy already at the stage when the loop radius is only slightly larger than the radius of the core. Consider, for example, that this has to occur when $r = 2r_0$. The condition for spontaneous formation of the loops is then $\sigma = \mu b / (4\pi(1-\nu)r_0)(\ln 16 - 1)$. Since $r_0 \approx b$, the stress needed for the dislocation nucleation is (taking $\nu = 1/3$) $\sigma \approx 0.2\mu$, which is of the same order of magnitude as the ideal shear strength of materials. This is a very high stress, and in most metallic, covalent, and even in ionic materials the plastic flow and intensive dislocation multiplication occur at stresses three to five orders of magnitude lower. Thus, homogeneous nucleation of individual dislocation loops cannot be the usual mechanism of dislocation nucleation. However, a collective homogeneous nucleation at finite temperatures by the mechanism akin to the Kosterlitz–Thouless transition is a possibility albeit not yet unequivocally proven.

An alternative heterogeneous mechanism, known as the Frank–Read source, requires stresses much lower than the ideal shear strength of the material. This process of generation of dislocations is shown schematically in Figure 1. A dislocation lying in a glide plane is pinned at two points (marked by bold dots), for example owing to intersection with dislocations in different glide planes.

Figure 1 Successive stages in the operation of a double-ended Frank–Read dislocation source.

If these points are fixed, the dislocation can bow out under the action of a shear stress and adopt the successive configurations shown in (Figure 1b–1f). Eventually the two segments of opposite sign meet (Figure 1e), mutually annihilate, and a closed dislocation loop is produced (Figure 1f). A line segment between the pinning points remains available to repeat the whole process. The bowing out of the dislocation is opposed by the line tension of the dislocation that pulls the dislocation back by the force (per unit length) equal to $\tau\kappa$, where κ is the curvature of the line. In the isotropic case, the curvature is the largest when the dislocation forms the half-circle of radius d , where $2d$ is the separation of the pinning points (Figure 1c). Thus, the condition for the onset of the operation of the Frank–Read source is $\sigma b = \tau/d$. Taking $\tau = \mu b^2/2$, the stress needed for the operation of the source is $\sigma = \mu b/2d$. Since d may be three or four orders of magnitude larger than b , this leads to a stress that is several orders of magnitude lower than the ideal shear strength of the material, in agreement with experimental observations. Hence, Frank–Read-type dislocation sources, the geometrical configurations of which may be more complex than that in Figure 1, represent the principal mechanism of dislocation multiplication during deformation. Nevertheless, homogeneous dislocation nucleation may still occur in the case where no sources are available. However, the stresses then reach the level of the ideal shear strength. This occurs, for example, in nanoindentation.

Dislocation Dissociation and Stacking Faults

A vital characteristic of dislocations in crystalline materials is their possible dissociation into partial dislocations with Burgers vectors smaller than the lattice vector. Such dislocation splitting can occur if the displacements corresponding to the Burgers vectors of the partials lead to the formation of metastable planar faults which then connect the partials. The reason for the splitting is, of course, the decrease of the dislocation energy when it is divided into dislocations with smaller Burgers vectors. For example, if the dislocation with the Burgers vector $\mathbf{b}$ splits into two partials with Burgers vectors $\mathbf{b}_1$ and $\mathbf{b}_2$, such that $\mathbf{b} = \mathbf{b}_1 + \mathbf{b}_2$ and the angle between the vectors $\mathbf{b}_1$ and $\mathbf{b}_2$ is acute, then $b^2 > b_1^2 + b_2^2$. Since the elastic energy of a dislocation is proportional to the square of its Burgers vector, the self-energy of the total dislocation is larger than that of two partials. This is the basis of the so-called b^2 criterion for estimation whether a dissociation is energetically favorable. However, to determine the energy balance precisely, one has to consider also the interaction energy between partials and the energy of the planar fault formed between them. A simple example is splitting of $1/2\langle 110 \rangle$ dislocations into two Shockley partials with the Burgers vectors $1/6\langle 112 \rangle$ on $\{111\}$ planes. The planar fault formed by the $1/6\langle 112 \rangle$ displacement is an intrinsic stacking fault. The stacking of $\{111\}$ planes in an ideal face-centered cubic (f.c.c.) lattice can be described as a repeat sequence ...ABCABCABC... and the $1/6\langle 112 \rangle$ displacement between layers B and C produces the stacking sequence ...ABCAB|ABCABC...; this corresponds to the stacking fault marked by |.

In general, stacking-fault-like defects can be very conveniently analyzed using the notion of γ -surfaces (Stacking-fault-like defects include not only stacking faults but also other planar defects such as antiphase domain boundaries and complex stacking faults encountered in ordered alloys and compounds). To introduce the idea of γ -surfaces, a generalized stacking fault is defined first: imagine that the crystal is cut along a given crystallographic plane and the upper part displaced with respect to the lower part by a vector $\mathbf{u}$, parallel to the plane of the cut, as shown in Figure 2. The fault created in this way is called the “generalized stacking fault” and it is not, in general, metastable. The energy of such fault, $\gamma(\mathbf{u})$, can be evaluated using atomistic methods and/or density-functional theory based approaches; relaxation perpendicular to the fault has to be carried in such calculations. Repeating this procedure for various vectors $\mathbf{u}$ within the repeat cell of the given crystal plane, an energy–displacement surface can be constructed, commonly called the γ -surface. The local minima on this surface determine the displacement vectors of all possible metastable stacking-fault-like defects, and the values of γ at these minima are the energies of these faults.

Symmetry arguments can be utilized to assess the general shape of these surfaces. If a mirror plane of the perfect lattice perpendicular to the plane of the generalized stacking fault passes through the point corresponding to a displacement $\mathbf{u}$, the first

Figure 2 Formation of the generalized stacking fault.

derivative of the γ -surface along the normal to this mirror plane vanishes owing to the mirror symmetry. This implies that the γ -surface will possess extrema (minima, maxima, or inflexions) for those displacements, for which there are at least two nonparallel mirror planes of the perfect lattice perpendicular to the fault. Whether any of these extrema corresponds to minima, and thus to metastable faults, can often be ascertained by considering the change in the nearest neighbor configuration produced by the corresponding displacement. Hence, the symmetry-dictated metastable stacking-fault-like defects can be ascertained on a crystal plane by analyzing its symmetry. Such faults are then common to all materials with a given crystal structure. The intrinsic stacking faults in f.c.c. crystals are symmetry-dictated since three mirror planes of the $\{101\}$ type pass through the points that correspond to the displacements $1/6\langle 112 \rangle$. However, other minima than those associated with symmetry-dictated extrema may exist in any particular material. These cannot be anticipated on crystallographic grounds, and their existence depends on the details of atomic interactions and can only be revealed by calculations of the γ -surface.

The primary significance of the dislocation dissociation is that it determines uniquely the slip planes, identified with the planes of splitting and corresponding stacking-fault-like defects, and, consequently, the operative slip systems. The fact that $\{111\}$ planes are the slip planes in f.c.c. materials is a typical example. As discussed above, metastable stacking faults always exist on these planes and since their energy is in many cases relatively low, dislocations split in $\{111\}$ planes and are confined to them.

Dislocation Cores

It has already been mentioned above that every crystal dislocation possesses a core region in which the linear elasticity does not apply and the structure and properties of the core can only be fully understood when the atomic structure is adequately accounted for. When a dislocation glides, its core undergoes changes that are the source of an intrinsic lattice friction. This friction is periodic with the period of the crystallographic direction in which the dislocation moves. The applied stress needed to overcome this friction at 0 K temperature is called the Peierls stress and the corresponding periodic energy barrier is called the Peierls barrier.

In general, the dislocation core structure can be described in terms of the relative displacements of atoms in the core region. These displacements are usually not distributed isotropically but are confined to certain crystallographic planes. Two distinct types of dislocation cores have been found, depending on the mode of the distribution of significant atomic displacements. When the core displacements are confined to a single crystallographic plane, the core is planar (a more complex planar core, called zonal, may be spread into several parallel crystallographic planes of the same type). Dislocations with such cores usually glide easily in the planes of the core spreading and their Peierls stress is commonly low. In contrast, if the core displacements spread into several nonparallel planes of the zone of the dislocation line, the core is nonplanar, extended spatially. The glide planes of dislocations with such cores are often not defined uniquely, their Peierls stress is high, and their glide well below the melting temperature is enabled by thermal activation over the Peierls barriers.

A planar dislocation core can be regarded as a continuous distribution of dislocations in the plane of the core spreading. The reason for the core extension is the decrease of the dislocation energy when it is redistributed into dislocations with smaller Burgers vectors. Such approach to the analysis of the dislocation core is the basis of the Peierls–Nabarro model. If the coordinate system in the plane of the core spreading is chosen such that the axes x_1 and x_2 are parallel and perpendicular to the dislocation line, respectively, the corresponding density of continuous distribution of dislocations has two components: $\rho_\alpha = \partial u_\alpha / \partial x_2$ ($\alpha = 1, 2$), where u_α is the α -component of the displacement vector $\mathbf{u}$ in the x_1, x_2 plane. Owing to the dislocation distribution, the displacement $\mathbf{u}$ increases gradually in the direction x_2 from zero to the Burgers vector so that $\int_{-\alpha}^{+\alpha} \rho_\alpha dx_2 = b_\alpha$, where b_α is the corresponding component of the Burgers vector. In the continuum approximation, the elastic energy of such dislocation distribution can be expressed as the interaction energy of the dislocation distribution with itself:

$$E_{el} = \sum_{\alpha, \beta=1}^2 \int_{-\alpha}^{+\alpha} \int_{-\alpha}^{+\alpha} K_{\alpha\beta} \rho_\alpha \rho_\beta \ln(|x_2 - x'_2|) dx_2 dx'_2$$

where $K_{\alpha\beta}$ are constants depending on the elastic moduli and orientation of the dislocation line. On the atomic scale, the displacement across the plane of the core spreading causes a disregistry that leads to an energy increase. The displacement $\mathbf{u}$ produces locally a generalized stacking fault, and in the local approximation the energy associated with the disregistry can be approximated as

$$E_\gamma = \int_{-\alpha}^{+\alpha} \gamma(u) dx_2$$

where $\gamma(u)$ is the energy of the γ -surface for the displacement $\mathbf{u}$. The continuous distribution of dislocations describing the core structure is then found by the functional minimization of the total energy $E_{tot} = E_{el} + E_\gamma$ with respect to the displacement $\mathbf{u}$. When the displacement vector is always parallel to the Burgers vector, the Euler equation corresponding to the condition $\delta E_{tot} = 0$ leads to the well-known Peierls equation

$$K \int_{-\alpha}^{+\alpha} \frac{1}{x_2 - x'_2} \frac{du}{dx'_2} dx'_2 = - \frac{\partial \gamma}{\partial u}$$

where u is the displacement in the direction of the Burgers vector and K is a constant depending on the elastic moduli and orientation of the dislocation line; in the isotropic elasticity K is given earlier. In the original Peierls–Nabarro model, $\partial\gamma/\partial u$ was taken as a sinusoidal function and the Peierls equation then has an analytical solution

$$u = \frac{b}{2\pi} \tan^{-1} \left(\frac{x_2}{\zeta} \right)$$

where 2ζ measures the width of the core (for $-\zeta > x_2 > \zeta$, the disregistry is greater than half its maximum value) and it is proportional to the separation of the crystal planes into which the core spreads. The Peierls stress evaluated in the framework of this model is

$$\tau_p = \frac{2\mu}{\alpha} \exp(-4\pi\zeta/b)$$

where μ is the shear modulus and α a constant of the order of 1. This stress is very small even when the core is very narrow; for example, if $\zeta = b$, $\tau_p \approx 10^{-5}\mu$. This is a general characteristic of the planar cores and this is the reason why in f.c.c. metals, in which dislocations possess planar cores, the Peierls stress is practically negligible.

The nonplanar cores can be divided into two classes: crossslip and climb cores. In the former case, the core displacements lie in the planes of core spreading, whereas in the latter case, they possess components perpendicular to the planes of spreading. Climb cores are less common and are usually formed at high temperatures by a climb process. The best-known example of the crossslip core is the core of the $1/2[111]$ screw dislocations in body-centered cubic (b.c.c.) metals that is spread into three $\{110\}$ planes intersecting along the $\langle 111 \rangle$ direction. Figure 3 shows two alternate structures of such core. The core shown in Figure 3a is spread asymmetrically into the $(\bar{1}01)$, $(0\bar{1}1)$, and $(\bar{1}10)$ planes that belong to the $[111]$ zone and is not invariant with respect to the $[10\bar{1}]$ diad and another energetically equivalent configuration, related by this symmetry, operation exists. The core in Figure 3b is invariant with respect to the $[10\bar{1}]$ diad. These core structures were found by atomistic calculations employing (1) central-force many-body potentials and (2) a tight binding and/or density-functional theory based approach, respectively. Atomistic calculations employing appropriate descriptions of atomic interactions are the principal tool for investigations of such cores since direct observations are often outside the limits of experimental techniques. The example presented here shows that the structure of such cores is not determined solely by the crystal structure but may vary from material to material even when they crystallize in the same structure. The Peierls stress of dislocations with these cores is commonly several orders of magnitude higher than that of dislocations with planar cores. Furthermore, the movement of the dislocations is frequently affected not just by the shear stress parallel to the Burgers vector in the slip plane but by other stress components. Thus, the deformation behavior of materials with nonplanar dislocation cores may be very complex, often displaying unusual orientation dependencies and breakdown of the Schmid law. The nonplanar dislocation cores are the more common the more complex is the crystal structure, and thus these cores are more prevalent than planar cores. In this respect, f.c.c. materials (and also some hexagonal close-packed (h.c.p.) materials with basal slip) in which the dislocations possess planar cores and, consequently, the Peierls stress is very low, are a special case rather than a prototype for more complex structures.

Additional complex features of the dislocation core structures arise in covalent crystals where the breaking and/or readjustment of the bonds in the core region may be responsible for a high lattice friction stress, and in ionic solids where the cores can be charged which then strongly affects the dislocation mobility. Such dislocation cores affect not only the plastic behavior but also electronic and/or optical properties of covalently bonded semiconductors and ionically bonded ceramic materials.

Figure 3 Two alternate core structures of the $1/2[111]$ screw dislocation depicted using differential displacement maps. The atomic arrangement is shown in the projection perpendicular to the direction of the dislocation line ($[111]$) and circles represent atoms within one period. The $[111]$ (screw) component of the relative displacement of the neighboring atoms produced by the dislocation is represented by an arrow between them. The length of the arrows is proportional to the magnitude of these components. The arrows, which indicate out-of-plane displacements, are always drawn along the line connecting neighboring atoms and their length is normalized such that it is equal to the separation of these atoms in the projection when the magnitude of their relative displacement is equal to $1/6[111]$.

Introduction

Crystal lattice dynamics is based on the concept of phonons, that is, weakly interacting waves of atomic (or ionic) vibrations and corresponding quasiparticles (according to a corpuscular-wave dualism of the quantum physics, any excitation wave in a system can also be described as a particle). Due to the smallness of typical atomic displacements, $\bar{u}$ in crystals in comparison with interatomic distances d , one can pass rigorously from a problem of strongly interacting “particles” forming the crystal (atoms, ions, or molecules) to a problem of weakly interacting “quasiparticles” (phonons). In the leading order in the smallness parameter $\eta = \bar{u}/d$, the crystal lattice dynamics and thermodynamics can be described in terms of an ideal phonon gas (harmonic approximation). For the ground state, the harmonic approximation can be justified rigorously on the basis of the adiabatic (Born–Oppenheimer) approximation of quantum mechanics due to the smallness of the ratio of the electron mass, m to the atomic (or ionic) mass M . With the increase in temperature T , the parameter η increases as well; however, due to a semi-empirical Lindemann criterion $\eta \simeq 0.1$ at the melting point $T = T_m$, higher-order contributions to thermodynamic properties are usually small up to the melting temperature. This statement is true for most of the average characteristics. At the same time, for some peculiar modes, the harmonic approximation can be completely inadequate, especially in the vicinity of some structural transformations, such as ferroelectric phase transitions or martensitic transformations in metals (soft modes). It is not sufficient also for quantum crystals, such as solid He^3 and He^4 . Even in a generic case, some phenomena can be understood only beyond the picture of the ideal phonon gas, which means beyond the harmonic approximation. All these phenomena are called anharmonic. There are anharmonic effects in the crystal lattice thermodynamics (thermal expansion, temperature dependences of elastic moduli, etc.), kinetics (phononphonon scattering processes which are responsible for the thermal conductivity of insulators), and dynamics (phonon damping and temperature dependences of the phonon frequencies measured by the inelastic neutron scattering method).

Formulation of the Problem

In the adiabatic approximation, one can split the quantum-mechanical problem of the crystal into an electronic (a solution of the Schrödinger equation for fixed coordinates of nuclei $\{\mathbf{r}_j\}$) and a nuclear one which is the base of the theory of crystal lattice properties. Keeping in mind the smallness of the atomic displacements $\eta < 1$, one can expand the energy of the nuclei $V(\{\mathbf{r}_j\})$ into the displacement vectors $\mathbf{u}_j = \mathbf{r}_j - \mathbf{R}_j$, $\mathbf{R}_j$ being the equilibrium lattice positions:

$$V(\{\mathbf{r}_j\}) = V_0 + \frac{1}{2} \sum_{j_1 j_2 \alpha_1 \alpha_2} V_{j_1 j_2}^{\alpha_1 \alpha_2} \mathbf{u}_{j_1}^{\alpha_1} \mathbf{u}_{j_2}^{\alpha_2} + \frac{1}{6} \sum_{j_1 j_2 j_3 \alpha_1 \alpha_2 \alpha_3} V_{j_1 j_2 j_3}^{\alpha_1 \alpha_2 \alpha_3} \mathbf{u}_{j_1}^{\alpha_1} \mathbf{u}_{j_2}^{\alpha_2} \mathbf{u}_{j_3}^{\alpha_3} + \dots, V_{j_1 \dots j_n}^{\alpha_1 \dots \alpha_n} = \left(\frac{\partial^n V}{\partial \mathbf{u}_{j_1}^{\alpha_1} \dots \partial \mathbf{u}_{j_n}^{\alpha_n}} \right)_{\mathbf{u}=0} \quad [1]$$

where α_j are Cartesian indices and the linear term is absent due to the equilibrium conditions. The harmonic approximation corresponds to taking into account only the quadratic term in the expansion [1]. Then the nuclear Hamiltonian, which is the sum of the potential energy V and the kinetic energy of nuclei, can be represented as a sum of the Hamiltonians of independent oscillators (phonons) by the transformation

$$\mathbf{u}_j = \sum_{\lambda} \sqrt{\frac{\hbar}{2M_j N_0 \omega_{\lambda}}} A_{\lambda} \mathbf{e}_{\lambda} \exp(i\mathbf{q}\mathbf{R}_j), A_{\lambda} = b_{\lambda} + b_{-\lambda}^{\dagger} \quad [2]$$

where N_0 is the number of unit cells in the crystal, M_j is the mass of the j th nucleus, $\lambda \equiv \mathbf{q}\xi$ are the phonon quantum numbers ($\mathbf{q}$ is the wave vector running the Brillouin zone and ξ is the polarization index, $-\lambda \equiv -\mathbf{q}\xi$), $\mathbf{e}_\lambda$ is the polarization vector, b_λ and $b_\lambda^\dagger$ are the annihilation and creation phonon operators. In the phonon representation, the total Hamiltonian of the crystal lattice has the form

$$H = V_0 + H_0 + \sum_{k=3}^{\infty} H^{(k)}, H_0 = \sum_{\lambda} \hbar \omega_{\lambda} \left(b_{\lambda}^\dagger b_{\lambda} + \frac{1}{2} \right), H^{(k)} = \sum_{\lambda_1 \dots \lambda_k} \frac{\Phi_{\lambda_1 \dots \lambda_k}^{(k)}}{k!} A_{\lambda_1} \dots A_{\lambda_k} \quad [3]$$

where H_0 is the Hamiltonian of the ideal phonon gas (the harmonic approximation) and the multiphonon scattering matrix elements $\Phi_{\lambda_1 \dots \lambda_k}^{(k)}$ are proportional to the k th derivatives of the potential energy and the factors $\sqrt{\hbar/2M_j\omega_{\lambda_i}}$. These matrix elements describe the processes of phonon–phonon interaction, such as a merging of two phonons into one or, vice versa, a decay of a phonon into two ($k=3$), scattering of two phonons into two new states ($k=4$), etc. The anharmonic effects connected with these interactions are called self-anharmonic. There is also another kind of anharmonic effect which is connected to the dependence of the phonon frequencies ω_λ on the interatomic distances in the Hamiltonian H_0 . These effects are called quasiharmonic. They are characterized by the microscopic Grüneisen parameters

$$\gamma_\lambda = - \frac{\partial \ln \omega_\lambda}{\partial \ln \Omega} \quad [4]$$

where Ω is the crystal volume. For noncubic crystals, the dependence of ω_λ on shear deformations should also be considered. The point is that for harmonic oscillators described by the quadratic potential energy and, correspondingly, by linear interatomic forces, the frequencies are not dependent either on the amplitudes of oscillations or on the equilibrium positions. Due to nonlinear (anharmonic) effects, there are renormalizations of the frequencies. Up to the lowest order η^2 , one should take into account the quasiharmonic effects and the self-anharmonic effects with $k=3$ and 4.

Thermodynamics

Thermal Expansion

Thermal expansion, characterized by the coefficient,

$$\alpha_p = \frac{1}{\Omega} \left(\frac{\partial \Omega}{\partial T} \right)_p \quad [5]$$

(T is the temperature and p is the pressure) equals to zero in harmonic approximation. This can be easily proved from the Gibbs distribution for the potential energy V , which is quadratic in the atomic displacements $\mathbf{u}_j$ (and, moreover, if it is just an arbitrary even function of $\mathbf{u}_j$). It can be calculated by using the known thermodynamic identity

$$\left(\frac{\partial \Omega}{\partial T} \right)_p = - \left(\frac{\partial S}{\partial p} \right)_T \quad [6]$$

where S is the entropy; as a consequence, due to the third law of thermodynamics, the thermal expansion coefficient should vanish at $T \rightarrow 0$. If one calculates the entropy in harmonic approximation but with the phonon frequencies dependent on the volume (quasiharmonic approximation), one can derive the Grüneisen law

$$\alpha_p = \frac{\gamma(T) C_V(T)}{\Omega B_T} \quad [7]$$

where $B_T = -\Omega(\partial p/\partial \Omega)_T$ is the isothermal bulk modulus,

$$\gamma(T) = \frac{\sum_{\lambda} \gamma_{\lambda} C_{\lambda}}{\sum_{\lambda} C_{\lambda}}, C_{\lambda} = \left(\frac{\hbar \omega_{\lambda}}{k_B T} \right)^2 \frac{\exp(\hbar \omega_{\lambda}/k_B T)}{[\exp(\hbar \omega_{\lambda}/k_B T) - 1]^2} \quad [8]$$

is the macroscopic Grüneisen parameter (which is temperature independent assuming that $\gamma_{\lambda} = \text{const}$ and $C_V(T) = k_B \sum_{\lambda} C_{\lambda}$ is the constant-volume lattice heat capacity. It follows from eqn [7] that the temperature dependence of the thermal expansion coefficient at low and high temperatures is the same as for the heat capacity: $\alpha_p \sim T^3$ at $T \ll \theta_D$ (θ_D is the Debye temperature) and $\alpha_p \simeq \text{const}$ at $T \gg \theta_D$.

For noncubic crystals, one should introduce parameters characterizing the anisotropy of the thermal expansion $\alpha_i = \partial u_i / \partial T$, where u_i are different deformations, for example, for uniaxial crystals with c -axis different from a - and b -axes, one can introduce $du_1 = d \ln \Omega$ and $du_2 = d \ln(c/a)$. As a generalization of eqn [6], one can prove from the equilibrium conditions at finite temperatures

$$\alpha_i = \sum_j (B^{-1})_{ij} \left(\frac{\partial S}{\partial u_j} \right)_T \quad [9]$$

where $B_{ij} = (1/\Omega)(\partial^2 F / \partial u_i \partial u_j)$ is the matrix of isothermal elastic moduli and F is the free energy. In particular, for the uniaxial crystals

$$\begin{aligned} \left(\frac{\partial \ln c}{\partial T} \right) &= \frac{1}{3BB_{22}} \left[(B_{22} - 2B_{12}) \frac{\partial S}{\partial u_1} + (2B_{11} - B_{12}) \frac{\partial S}{\partial u_2} \right] \\ \left(\frac{\partial \ln a}{\partial T} \right) &= \frac{1}{3BB_{22}} \left[(B_{22} + 2B_{12}) \frac{\partial S}{\partial u_1} - (B_{11} + B_{12}) \frac{\partial S}{\partial u_2} \right] \end{aligned} \quad [10]$$

where $B = B_{11} - B_{12}^2/B_{22}$ is the bulk modulus of the uniaxial crystal.

Temperature Dependence of Elastic Moduli

Temperature dependence of the elastic moduli B_{ij} is another important anharmonic effect. This temperature dependence in quasi-harmonic approximation results from the ideal phonon gas contribution to the free energy, $F_{ph} = -k_B T \sum_{\lambda} \ln[2 \sinh(\hbar \omega_{\lambda}/2k_B T)]$, and from the volume dependence of the electronic contributions to the moduli. As a result, both terms behave as $\delta B_{ij} \propto -T^4$ at $T \ll \theta_D$ and $\delta B_{ij} \propto -T$ at $T \gg \theta_D$. Normally, this contribution is negative (elastic moduli decrease with the temperature increase), but for some shear moduli in peculiar cases an opposite behavior sometimes takes place (acoustic soft modes), usually near the structural phase transitions. Empirically, for many cubic crystals the trigonal shear modulus B_{44} at the melting point is 55% of its value at zero temperature (Varshni melting criterion).

Lattice Heat Capacity at High Temperatures

In harmonic approximation, the molar constant-volume heat capacity at $T \gtrsim \theta_D$ is independent of both the temperature and the chemical composition of the crystal: $C_V = 3R$ (Dulong–Petit law, $R \approx 8.3144 \text{ J mol}^{-1} \text{ K}^{-1}$ is the gas constant). Self-anharmonic effects lead to linear temperature dependence of the heat capacity, $\delta C_V \sim R\eta^2 \sim R(k_B T/E_{coh})$ where E_{coh} is a typical energy of the chemical bonding. These terms arise from both three-phonon and four-phonon processes (the second-order perturbation effect in $H^{(3)}$ and the first-order one in $H^{(4)}$, see eqn [3]):

$$C_V^{(3)} = \frac{4k_B^2 T}{3} \sum_{kq\xi\eta\zeta} \frac{|\Phi_{\xi k; \eta q; \zeta, -k-q}^{(3)}|^2}{\hbar^3 \omega_{\xi k} \omega_{\eta q} \omega_{\zeta, -k-q}} \quad [11]$$

$$C_V^{(4)} = -k_B^2 T \sum_{kq\xi\eta\zeta} \frac{\Phi_{\xi k; \xi, -k; \eta q; \eta, -q}^{(4)}}{\hbar^2 \omega_{\xi k} \omega_{\eta q}} \quad [12]$$

The three-phonon contribution [11] is always positive (the growth of C_V with the increase in the temperature), whereas the four-phonon one [12] can be, in principle, of arbitrary sign. Experimental separation of the self-anharmonic contribution to the lattice heat capacity is a difficult problem since it has, in general, the same order of magnitude and temperature dependence as the difference

$$C_P - C_V = T\Omega B_T \alpha_p^2 \quad [13]$$

(C_P is the experimentally measurable heat capacity at a constant pressure) and, in metals, as the electron heat capacity.

Phonon Spectra and Damping

Temperature Dependences of Phonon Frequencies

According to classical mechanics, for a generic nonlinear system, the oscillation frequencies are dependent on the oscillation amplitudes. Therefore, one can expect that anharmonic effects lead to the temperature-dependent phonon spectra, due to growth of average oscillation amplitudes with the increase in temperature. In quantum terms, the same effect can be described as an appearance of the phonon self-energy due to the phonon–phonon interaction processes. Up to the second order in the smallness parameter η , the temperature shift of the phonon frequency ω_{λ} is determined by the following expression:

$$\Delta \omega_{\lambda} = \Delta_{\lambda}^{(qh)} + \Delta_{\lambda}^{(3)} + \Delta_{\lambda}^{(4)} \quad [14]$$

where $\Delta_{\lambda}^{(qh)} = -\gamma_{\lambda} \Delta \Omega(T)/\Omega$ is the quasi-harmonic contribution due to the temperature dependence of the crystal volume $\Omega(T)$, and $\Delta_{\lambda}^{(3)}$ and $\Delta_{\lambda}^{(4)}$ are the contributions of the three-phonon and four-phonon processes, correspondingly:

$$\Delta_{\xi k}^{(3)} = -\frac{1}{2\hbar^2} \mathcal{P} \sum_{q\eta\zeta} \left| \Phi_{\xi k; \eta q; \zeta, -k-q}^{(3)} \right|^2 \times \left(\frac{1 + N_{\eta q} + N_{\zeta, k+q}}{\omega_{\eta q} + \omega_{\zeta, k+q} + \omega_{\xi k}} + \frac{1 + N_{\eta q} + N_{\zeta, k+q}}{\omega_{\eta q} + \omega_{\zeta, k+q} + \omega_{\xi k}} + \frac{N_{\eta q} - N_{\zeta, k+q}}{\omega_{\zeta, k+q} - \omega_{\eta q} - \omega_{\xi k}} - \frac{N_{\eta q} - N_{\zeta, k+q}}{\omega_{\eta q} - \omega_{\zeta, k+q} - \omega_{\xi k}} \right) \quad [15]$$

$$\Delta_{\xi k}^{(4)} = \frac{1}{2\hbar} \sum_{q\eta} \Phi_{\xi k; \xi, -k; \eta q; \eta, -q}^{(4)} (1 + 2N_{\eta q}) \quad [16]$$

where $\mathcal{P}$ is the principal value symbol and $N_{\lambda} = (\exp \hbar \omega_{\lambda}/k_B T - 1)^{-1}$ is the Planck function. At high temperatures $T \gtrsim \theta_D$, one can use the classical asymptotic $N_{\lambda} \simeq k_B T/\hbar \omega_{\lambda}$ and see that all three contributions in eqn [14] are linear in temperature. Usually, the

Figure 1 Temperature dependences of the frequency shifts (upper panel) and phonon damping (lower panel) for different phonon modes at the symmetric points of the Brillouin zone for face-centered cubic (f.c.c) phase of calcium. $\omega_{pl} = (4\pi Ze^2/M\Omega_0)^{1/2}$ is ionic plasma frequency, Z , M , and Ω_0 are the valency, ionic mass, and atomic volume, respectively, $T_{pl} = \hbar\omega_{pl}/k_B = 476\text{K}$ is the corresponding temperature. Asterisks and hearts label different phonon modes for L point, circles and triangles for W point, and squares and diamonds for X point. (From Katsnelson MI, Trefilov AV, Khlopkin MN, and Khromov KYu (2001) *Philosophical Magazine B* 81: 1893.)

phonon frequencies decrease with the temperature increase; a typical behavior is shown in Figure 1 (upper panel). However, for the soft modes, $d\omega_\lambda/dT > 0$, as it is illustrated by Figure 2. In the framework of the perturbation theory, this behavior is connected with the contribution $\Delta_\lambda^{(4)}$.

Phonon Damping

Beyond the harmonic approximation, the phonons cannot be considered as stable quasiparticles; for example, due to the three-phonon processes, they can decay into couples of other phonons. As a result, the phonon damping arises (which can be measured experimentally as a half-width of phonon peaks in inelastic neutron scattering spectra). In the lowest-order perturbation theory, the damping, or the inverse phonon lifetime, is equal to

$$\Gamma_{\xi k} = \frac{\pi}{2\hbar^2} \sum_{q\eta\zeta} |\Phi_{\xi k; \eta q; \zeta, -k-q}^{(3)}|^2 \left\{ (1 + N_{\eta q} + N_{\zeta, k+q}) \times \delta(\omega_{\eta q} + \omega_{\zeta, k+q} - \omega_{\xi k}) + (N_{\eta q} - N_{\zeta, k+q}) \times [\delta(\omega_{\zeta, k+q} - \omega_{\eta q} - \omega_{\xi k}) - \delta(\omega_{\eta q} - \omega_{\zeta, k+q} - \omega_{\xi k})] \right\} \quad [17]$$

The delta functions in eqn [17] correspond to the energy and momentum conservation laws for the decay processes. At high temperatures $T \gtrsim \theta_D$, the damping is linear in T (see Figure 1, lower panel). Note that, both the damping and the frequency shift do not vanish at $T=0$ where all $N_\lambda = 0$. These residual effects are due to quantum zero-point oscillations; they are of the order of $\sqrt{m/M}$ and small, in general (with the exception of the quantum crystals). For acoustic phonons with $q \rightarrow 0$, the damping [17] is linear in q , as well as in the phonon frequency; however, this is not true for the case $ql \ll 1$, where l is the phonon mean free path. For this regime, according to general hydrodynamics consideration, the damping behaves like $q^2 l$.

Figure 2 Temperature dependence of the phonon frequencies of the $T[\xi\xi\xi]$ phonon branch in (f.c.c) lanthanum in the soft mode region. (From Stassis C, Smith GS, Harmon BN, Ho KM, and Chen Y (1985) *Physical Review B* 31: 6298.)

For strongly anharmonic modes, the phonon damping can be comparable with the frequency; phonons are not well-defined in such a situation (high-temperature body-centered cubic (b.c.c) phases of Ti and Zr can be considered as examples). The perturbation theory reviewed here can also be insufficient under resonance conditions, where the frequency ratio for different phonons with the same wave vector is close to 1:2, 1:3, etc.

Transport Properties

If one neglects phonon–phonon interactions as well as phonon scattering by any defects (impurities, different isotopes, crystal surface, etc.) and by other quasiparticles (conduction electrons in metals, spin waves in magnetic crystals, etc.), the mean free path $l \rightarrow \infty$ which means, in particular, infinitely large thermal conductivity κ (any nonequilibrium distribution of the phonon momenta and energies conserves for an ideal phonon gas). This means that for the case of perfect, isotopically homogeneous, large enough insulating crystals, the anharmonic effects should determine the values and temperature dependences of both l and κ ; they are connected by a simple relation:

$$k = \frac{1}{3} \frac{C_V \bar{v} l}{\Omega} \quad [18]$$

where $\bar{v}$ is a characteristic sound velocity. In principle, the same processes of phonon decay which are responsible for $\Gamma_{\xi k}$ contribute to the mean free path. However, for a continuum medium theory, any process of phonon–phonon interaction cannot lead to a finite thermal conductivity, since the momentum is conserved at any individual interaction act and any redistribution of the momenta among the phonons cannot change the energy current of the phonon gas as a whole. In crystals, Umklapp processes are possible when the momentum is conserved with the accuracy of some nonzero reciprocal lattice vector $\mathbf{g}$, and only these processes lead to the relaxation of the energy current and to finite κ . The energy conservation law for the Umklapp processes results in the appearance of some finite activation energy so that $l \propto \exp(\text{const} \times \theta_D/T)$ at $T \rightarrow 0$. For the very small temperatures, when the phonon mean free path is larger than the crystal size L , one should replace $l \rightarrow L$ in eqn [18] and thus $\kappa \propto C_V \propto T^3$. For high temperatures $T \gg \theta_D$, one has $\kappa \propto l \propto 1/T$.

Introduction

Although some of the earliest artifacts from ancient civilizations bear witness to man's long history of utilization of ceramic materials, modern ceramic science is advancing at an unprecedented pace. Ceramics remained an art (often with closely guarded secrets) for the majority of recorded history, and has only in the past century become the science it is today. With the pressures of increasingly demanding high-tech applications, whether smaller, larger, hotter, tougher, cleaner, brighter, or smarter, ceramics are often the material of choice.

State-of-the-art characterization and fabrication techniques allow one to achieve a new level of understanding of atomic-scale processes and capability for manipulation of atomic structure. In effect, ceramics can often be built atom-by-atom, layer-by-layer.

That said, what are ceramics? The definition is becoming increasingly more difficult to articulate. For a significant fraction of society, the definition relates to the art of making and decorating pottery, or other items of 'baked' clay. However, from the viewpoint of the scientist or engineer, ceramics are often defined by the chemistry, behavior, and/or processing methods used to create them. For example, a definition might be: an artifact made of hard, brittle, electrically insulating material produced from nonmetallic minerals by firing at high temperatures. This definition specifies chemistry, properties, and processing. While this definition is accurate for a large fraction of ceramics, it is not all-inclusive, and examples of ceramics that do not conform to one or more parts of this definition are becoming increasingly common. There are examples of ceramics (some discussed here) that are not brittle and electrically insulating, or are not made from nonmetallic minerals, or not fired at high temperatures. As an example, ceramic superconductors are among the most conductive materials known. An acceptable, but not complete, definition might be a refractory, inorganic, and nonmetallic material. Even this attempt at description is flawed, as the boundaries between biology and ceramics blur.

The field of ceramics (and all materials) is often represented as the four corners of a tetrahedron labeled structure, properties, processing, and performance. In this article, an overview of current ceramic science and engineering is presented through discussion of properties, novel processing, and general trends, with examples of the applications that demonstrate these advancements. Structure and performance are addressed within the context of both the properties and processing of these advanced ceramics.

[☆]*Change History:* May 2015. K.P. Constant. In the 'Properties' section, the portion on transparent ceramics for ballistic protection was changed to a discussion on toughened glass for touch screens. The section on photonic bandgap materials was changed to a description of light transmitting concrete. In 'Processing' – '3D rapid prototyping' was changed to 'Additive Manufacturing.' In 'Trends,' computational materials was added. Table 1, Figure 1 and Figure 3 were deleted. New figures 1 and 2 were added. Figure 3 and Figure 5 are old figures.

Properties

Ceramics have long been associated with characteristic properties such as high hardness, high stiffness, resistance to high temperatures, and chemical inertness, but today's ceramics stretch conventional applications of ceramics beyond what in the past were considered their fundamental limitations. A huge body of work has been generated in the past quarter of a century, some of which is highlighted here with examples in which mechanical, electrical, and optical properties are critical. Although not represented in the examples below, ceramics are also often used in thermal and magnetic applications in which there are many examples of exciting and novel advances.

Mechanical/Structural

Ceramics are often used where high hardness is required but are usually limited by their lack of toughness. A number of innovations have improved upon this mechanical deficiency including those demonstrated in the development of high hardness, scratch resistant cover glass in handheld electronic devices. Toughness can also be improved by the use of hard coatings on tough substrates. Although carbide coatings have long been used for grinding and for cutting tools, even harder diamond coatings are becoming increasingly popular. Because the processing techniques required are the most novel aspect of that field, thin film diamond coatings are discussed in the 'processing' section.

Toughened, Scratch Resistant Glass for Screens

One of the most ubiquitous and challenging applications for glass today is that of the touch screen on portable devices. As these devices are often carried in pockets with coins and keys and often dropped, the demands on the performance of the glass are high. The primary mechanical requirements for such an application include that they be thin and light, have high transparency and scratch and impact resistance. The combination of these properties eliminates plastics because of the mechanical requirements, especially scratch resistance. The concept of toughening glass has been understood for many centuries. In fact, Prince Rupert's Drops, made by the thermal tempering of a drop of molten glass through rapid quenching in cold water, were first reported in the 17th century, though the underlying mechanism was not known. We now understand that the extreme rapid cooling places the surface of the glass in a state of mechanical compression, while the interior, cooling more slowly, is in tension. This compressive state is much stronger than unstressed glass and can also be induced chemically by ion exchange on the surface. Likewise, tempered sheet glass, made either by thermal quenching or by ion exchange has also been employed for well over a century, however significant advances continue to be made in both the development of the chemistry and the processing for the toughening of sheet glass. Current specialized glass can be produced with a hardness close to sapphire, which is 9 on the Mohs scale of hardness (compared to 7 for standard glass). A number of companies are manufacturing specialized toughened glasses, with the most well known being Gorilla Glass™, by Corning, which, according to their own literature, has been included in more than 3 billion devices. There is significant competition to produce the thinnest, toughest glass for smartphones and tablets.

While the specifics of the chemistry and processing remain a closely guarded industrial secret, in general, toughening is achieved through ion exchange. The initial glass is an aluminosilicate and is fabricated in sheets that are under a millimeter thick. The compressive stress is induced through the introduction of large ions into the surface of the glass by placing the glass in a molten potassium salt bath to replace sodium at approximately 400 °C. Other advances include antimicrobial and anti-smudge screens. Additionally, the materials must be compatible with the electrical requirements of touch screen functioning and optical transparency required for imaging. Emerging technologies promise a thin, strong, and flexible glass that can be wrapped around a device or structure. It has been reported that the chemistry and processing of some of these advanced glasses has been aided by computational modeling, a topic that will be addressed in 'Trends in Ceramic Materials'.

Beyond handheld devices but not yet available commercially, the super tough glass is also being investigated for other uses requiring larger pieces of glass, for example, in an automobile windshield. Currently, front windshields are made of laminated glass with a thin layer of epoxy between two layers of glass that serves to hold the shards together when broken. If glass toughened in the manner of that in current handheld devices, safer and better performing windshields are possible.

Electrical

Ceramics have long been used in the electronics industry as passive devices such as capacitors and insulators, and continue to be critical in those functions; however, in a variety of other electrical applications ceramics have become increasingly important. These include applications such as sensors (gas and chemical), conductive oxides (mixed conductors), and high-power/high-temperature electronic materials.

Fuel Cells

The exponential growth of portable electronic devices, cellular phones, computers, etc., provides strong motivation for the development of fuel cells and high-energy-density batteries. Fuel cells can provide clean energy for a variety of portable energy needs. Ceramic materials play a large role in the development of commercially viable products. Solid oxide, proton exchange membranes, and direct methanol fuel cells, lithium ion batteries, oxide-ion electrolytes, proton conductors, and mixed ionic/electronic conductors are all ceramic-based technologies. Solid oxide fuel cells (SOFC) are electrochemical energy conversion devices based on ion-conducting oxide electrolytes and are used in a broad spectrum of power-generation applications from small lightweight compact devices to large SOFC/turbine hybrid systems. The cells are solid-state devices operating at high temperatures. Because of this, there is great design flexibility (no liquid management required as in other 'batteries'). There are a variety of designs and geometries currently under investigation. The most common electrolyte materials include yttria (Y_2O_3) stabilized zirconia (ZrO_2), often called 8YSZ as it contains 8% yttria. This ceramic is ion conducting in both oxidizing and reducing environments. The most common anode material is a cermet (ceramic-metal composite) composed of Ni and 8YSZ. Nickel provides the electronic conductivity and catalytic activity while the 8YSZ supports the Ni particles and improves the anode thermal expansion match. The most common cathode material is a strontium-doped lanthanum manganite (Sr-doped $LaMnO_3$) – called LSM. The interconnect materials is usually doped $LaMnO_3$ or a metal that is stable in both oxidizing and reducing environments, however, metal interconnects require lower operating temperatures. The cost of these fuel cells is still a limiting factor in terms of broad applications and ways to reduce the costs are being aggressively sought, including reducing operating temperatures to allow the use of metallic interconnects and increasing the power density. Much effort has focused on the techniques to make dense ceramic coatings using the techniques of the semiconductor industry including chemical vapor deposition (CVD), electrochemical vapor deposition (EVD), physical vapor deposition (PVD), and screen printing as well as more traditional techniques such as sol-gel, tape casting, slurry casting, and centrifugal casting. The former techniques often have film quality and performance advantages, but also have low deposition rates (they are slow) and are costly. The latter techniques are efficient and economical but often result in lower-quality films. Increasingly important to the development on new fuel cell technologies is the advancement of modeling and simulation to achieve higher efficiency and energy conversion.

Optical

Although glass has long been used as an optically transparent material, and in fibers for communication and laser surgery, crystalline ceramics are gaining in importance in a variety of optical applications, including wireless technologies, microwave dielectrics, luminescent materials, and nonlinear optical materials. A novel blend of traditional and modern optical ceramics is that of light transmitting concrete. This application is a reminder that ceramics remain one of the most commonly used structural materials and that there is potential for advancement in this area as well as in more technology-based uses.

Translucent Concrete

While concrete has long been the workhorse for building infrastructure in cities and roads, it is not typically employed for its aesthetic appeal. Recently, a translucent concrete has been developed by combining traditional concrete with transparent components, usually fibers, to form an attractive, sustainable structural materials and design elements (Figure 1). Concrete has been used since the Roman times, and its basic components of sand or aggregate, cement and water are basically the same, although there are numerous modifications possible to effect structure and properties. In translucent concrete, optically transmitting fibers, typically

Figure 1 Architectural wall made concrete made translucent by the incorporation of glass fibers spanning the width of the wall (<http://dornob.com/see-through-light-transmitting-concrete-material/#axzz2v1i4eRSM>).

made from glass, but can also be made from polymers are embedded in the concrete during forming. If aligned across the thickness of the concrete, the fiber can transmit light.

Fabrication of translucent concrete can be accomplished in a number of ways. Although initially the fibers were placed manually, the process is now usually automated, reducing the cost of the product. The concrete used typically has a finer aggregate compared to traditional concrete and the fibers typically make up less than 5 vol% of the structure. The density, about 2200 kg m^{-3} , and compressive strength, 50 MPa are comparable to that standard concrete. The insulation value is slightly compromised by the presence of the fibers.

There are numerous functional advantages to this material, in addition to aesthetic appeal. Daylight could be used in building interiors without compromising privacy or energy efficiency as is usually the case with traditional windows. Additionally, as design elements, concrete and glass are considered sustainable materials as compared to wood.

Processing

The processing of advanced ceramics can be divided into two general classes with respect to the starting material – those that involve powders (powder processing) obtained by a variety of methods, and those that do not. In this section, recent advances in each method are presented through a specific example of each.

Additive Manufacturing of Ceramics

A recent advance in the forming stage of ceramic processing is that of additive manufacturing – also called 3D printing. There are a number of techniques that fall into this general category. The concept is to translate a 3D computer-generated design (CAD model) to a physical structure without the traditional step of making a mold in which to shape the product or the time and cost associated with machining a ceramic to desired dimensions. These methods can often make very complex geometries in a variety of shapes, sizes, surface finishes, and materials compositions. Most of these techniques rely on cutting 2D ‘slices’ from the 3D model and building them one on top of the other. These techniques usually begin with a bed of fine ceramic powder. Some techniques deposit binder into specific areas of the powder to ‘select’ the shape that remains after the entire shape is formed.

Other techniques use a laser or directed light to cure a polymer component added to the ceramic powder for that purpose. Layer upon layer of powder is added to the bed, each layer representing a subsequent 2D slice of the desired product. Regardless of technique, the result is that some ceramic powder is held in place as part of the shape to be made, while the remainder can be removed from the part, often by shaking. The powder is then further consolidated through heat treatment and sintering to form a monolithic ceramic part. These techniques have a variety of applications including those that are obvious – prototyping parts for testing before investing in tooling for mass production, but also less obvious, such as one-of-a-kind designs like prosthetic devices for biomedical uses.

Architectural Installations

In a recent demonstration of the power of 3-D printing for architectural applications, a number of powder 3-D printers were used to manufacture cement composite blocks that were individually labeled in the process to designate the block’s position in the final structure (Figure 2). Additionally, this technique can be used to fabricate very small components as discussed in the section on MEMS.

Figure 2 3D printed cement structure comprising 840 custom made blocks 9 ft high by 12 ft by 12 ft structure. (<http://ceramics.org/ceramic-tech-today/first-and-largest-3-d-printed-cement-structure-blooms-at-uc-berkeley-campus> (Published April 9, 2015))

Thin Film Techniques

A variety of thin film techniques have emerged from the semiconductor industry many involving ceramic materials including oxides, nitrides, and carbides. Most of them rely on liquid or gas-phase precursors and sophisticated control of chemistry, temperature, and pressures. These techniques often result in the growth of thin films of chemistries and morphologies not achievable in bulk form through traditional powder processing in similar temperature or pressure regimes (or sometimes in any temperature or pressure regime). One example of such techniques is presented here: CVD (chemical vapor deposition) of diamond thin films.

Diamond Coatings

Diamonds are truly an extreme material, having several properties that can only be described in superlatives: the hardest, the stiffest, the highest thermal conductor, highest sound propagation velocity, etc. Additionally, diamonds are very resistant to chemical corrosion, are biologically compatible, are optically transparent over a huge range of frequencies, and are excellent electrical insulators. However, their scarcity and availability only in single-crystal form have prevented widespread exploitation of most of these properties. With the exception of industrial diamonds created for cutting and grinding, the use of synthetic diamonds has been very limited. Rather than attempting to recreate nature's approach to diamond making (extreme temperatures and pressures), an alternative method has been discovered which has two significant advantages to nature's approach – easier processing resulting in a more convenient form. This method, which induces diamond growth by adding carbon atoms one-at-a-time to template, can be achieved without high temperature and pressure, and results in a thin film coating rather than isolated single crystals. Although this idea was conceived half a century ago (in the 1950s), it was not until the mid-1980s that good-quality films were grown. The concept, while relatively simple, presents numerous engineering challenges. At the heart of the technique is CVD. In this technique, a gas-phase chemical reaction occurs above a solid surface (often called a substrate as it forms the mechanical support for the resulting film). For the case of diamond films, a method of activating the gas-phase carbon-containing precursors is required. These include a hot filament or electrical discharge, or a combustion flame.

The most common method of diamond thin film growth uses methane, CH_4 , as a precursor gas. The gas concentration (usually diluted with H_2) and temperature of the substrate must be controlled to suppress the deposition of graphite or amorphous carbon. The method used is normally tailored to the desired application. For example, hot-filament techniques, which use a refractory metal (such as tungsten or tantalum), can be used to make good-quality diamond films for mechanical application, but they are not suitable for electronic applications because they contain metallic impurities from the filament that degrade the electrical properties.

Although requiring more expensive equipment than hot-filament growth, microwave plasma CVD reactors are currently the most widely used technique for diamond growth as they produce high-quality, chemically pure films. The substrate requirements for this process are significant. Among them, the substrate must be able to withstand the thermal and chemical conditions of the reactor, which precludes a large number of materials including all polymers, most metals, and many electronic materials. Also, because diamond has such a low thermal expansion coefficient, α , it is susceptible to delamination or flaking off a substrate which contracts more on cooling from the reaction temperature (usually about 700°C , so a substrate with a low α is required). In addition, the substrate must be able to form a carbide to some extent, as it has been suggested that the diamond films actually grow off an initial carbide interfacial layer. Currently silicon wafers are the most commonly used substrate material.

The chemical and physical processes that occur during thin-film growth are complex, but a very simplified model can be described by the schematic in [Figure 3](#). Not all reactions result in diamond; the process is slow and requires very careful control of both the chemical and physical conditions of the system. Much effort has been expended to understand the gas-phase chemistry of this system, and progress continues to date, resulting in improved, more efficient methods and higher-quality thin films.

Widespread application of diamond thin films is still limited by economic restrictions, but they are beginning to be used for cutting tools, thermal management where rapid heat dissipation is required, IR windows, and electronic devices. Recently, work has been reported which uses diamond thin films as an ideal substrate for integrating microelectronics with biological sensing functions. More on this topic is discussed later in the section Trends in Ceramic Materials.

A related recent development is that of diamond-like-carbon (DLC), a material that displays some, but not all, of the properties of a typical diamond. DLC is amorphous, but has hardness similar to crystalline diamond. This material is typically made in a high pressure diamond anvil cell, not by the thin film techniques described above.

Sustainable Processing

Increasingly strict legislative controls and escalating public concern for the local and global environment have affected most manufacturers of goods including those of ceramics as is testified to by the recent creation of ISO 14000 – a family of standards that is focused on certifying manufacturers and organizations in environmental management systems.

The environmental impact of any class of materials can be considered to have many aspects including: the source of raw materials, the energy and by-products associated with all stages of manufacture, and the disposal of the product when it is no longer useful. Ceramics are typically inert, and do not generally produce environmental hazards when disposed of, however, acquiring raw

Figure 3 Schematic of the physical and chemical processes occurring during diamond CVD. Reproduced with permission from May, P.W., 2000. Philosophical Transactions of the Royal Society of London. Series A 358, 473–495.

materials and refining and processing them can negatively impact the environment. Alternatively, ceramics can also be considered in terms of their use in remediation of the environmental impact of energy production. There has been increased awareness of each of these aspects in the manufacture of ceramics as well as in other materials. One such environmental application of ceramics has already been discussed in SOFC for clean energy storage solutions.

Eco-Ceramics

Environmentally friendly ceramics usually refer to those that undergo processing using environmentally benign solvents or resulting in harmless by-products. NASA reported the development of a method to make a SiC ceramic using wood as the preform to supply both the structure and the carbon for the process. In this technique, wood is pyrolyzed to form a carbon structure that is then infiltrated with silicon or silicon alloy. The result is a SiC-based ceramic with a microstructure imposed by the original wood and a shape that duplicates that of the pyrolyzed form (it is biomorphic). The structure (and therefore, properties) is tailorable by the choice of wood and can be further adjusted by laminating wood layers in various arrangements. This technique has been used to produce porous and nonporous structures of various compositions based on SiC. Since the initial work by NASA, other researchers have used this biomorphic approach to develop ultra high temperature ceramics composites of C/SiC–ZrC (**Figure 4**).

Concrete, as the most used construction material has a significant carbon ‘footprint’ – contributing 5% of global greenhouse gas emissions in the manufacture of Portland cement, a process typically fueled by coal. A recent report suggests that a reformulation could simultaneously improve the strength of concrete and reduce the energy costs of its production. The approach to reformulation utilizes a computationally derived database, revealing an emerging trend as cited in the next section.

Trends in Ceramic Materials

The most notable general trends in ceramics are those of the entire materials industry, and perhaps science and engineering as a whole, some of which have already been reflected in the examples given above. The first includes an ever-aggressive shrinking scale of our technological devices – requiring a more complete understanding of how material properties vary for very thin films and small grains (sometimes comprising fewer than 100 atoms). The second includes a focus on biological systems both from perspective of using natural systems to inspire and inform ceramic structure and processing, but also employing ceramics in biological systems (as prosthetic devices or drug delivery). Third, is the application of ever more powerful computing resources to apply to computational efforts to derive properties from first principles and model material behavior. Additionally computing power can enhance our ability to use combinatorial approaches and databases to explore novel formulations and manage and process enormous quantities of disparate data, as the example in the section on eco-ceramics describes. This trend that significantly impacts ceramics as well as all of materials science.

Nanotechnology/MEMS

As the scale of electronic devices shrinks, so has the scale of both the starting materials and the components of such devices. The trend toward nanoscale control has impacted ceramics as it has most fields of engineering and science. In a like manner, mechanical devices have continued to shrink to smaller and smaller dimensions, resulting in what is termed MEMS (micro-electromechanical systems). Ceramics are particularly well suited for MEMS applications in biological and chemical sensing systems (they tend to be chemically inert, even at high temperatures and severe environments). The advantages they bring to full-scale mechanical devices (e.g., engines) are also present at the microscale. Low density and high temperature capability make ceramics an attractive choice for high-speed devices such as nanoturbines. Ceramic MEMS have been made by microcasting a liquid ceramic precursor (e.g., polysilazanes) in a mold produced from photoresist by conventional lithographic methods (Figure 5). The resulting form is then pyrolyzed to convert to a Si–C–N amorphous ceramic. A second method of producing MEMS involves photopolymerization, a technique becoming increasingly widespread in the rapid prototyping industry. The technique involves adding a photo-initiator to a liquid ceramic precursor that will promote polymerization upon exposure to light of a specific wavelength. Shapes are constructed by exposing a layer of the precursor through a mask that has the desired shape. 3D structures are made by successive exposure to another layer, which has either the same, or a different geometry depending upon the desired result. Exposure can also be accomplished through the ‘writing’ of a directed laser beam. The exposed material polymerizes, and solidifies, allowing the remaining unexposed liquid to be washed away. In this way, a 3D structure can be created. The resolution achievable by such efforts is related to several factors both of the chemistry of precursor and photoinitiator and the physical characteristics of the mask or direct-write system. A similar approach to direct writing of structures is found in computer-controlled ink-jet printing of ceramic parts that is limited only by the length scale of the droplet. This technique relies on a colloidal, gel-based ink that forms a self-supporting structure. This technique, called robocasting has produced features as small as 100 μm , and has been made out of silica, alumina, lead-zirconate-titanate, and hydroxyapatite.

Bioceramics

Perhaps one of the most transformational trends in ceramics is that of bioceramics. Biology can take a variety of roles in the development of advanced ceramics from serving as the inspiration (or more directly, the template) for novel structures as discussed in the previous section on eco-ceramics to providing the motivation for the development of materials to be used in biomedical applications. Biomimicry is really nothing new – ancient people observed animals to learn the best methods to stalk prey, to identify safe foods to eat, and to predict weather changes, but until we developed the tools to examine nature at the microscopic (and now, atomic) level, we have made few efforts to copy nature at these length scales. Today, however, many scientists and engineers are again carefully studying natural materials striving to glean their secrets. Examples include the study of fracture toughness and interfacial design of the fiber-matrix ceramic composite that constitutes sea-urchin teeth and the self-assembled opal structure used as a template for photonic bandgap materials. Ceramics for biomedical applications have also become increasingly important in improving the quality of life for many of the worlds aging. Ceramics can be bioinert (such as alumina or zirconia) or can be

Figure 5 Left: Photoresist mold about 200 μm across. Right: The fired ceramic gear. (Am. Cer. Soc. Bull., 80 (5) 25, (2001).

bioactive (including hydroxyapatite and bioactive glass and glass ceramics). Ceramics have been used or are being developed for use in replacement joints for hips and knees, replacements for diseased or damaged bone, and reconstruction of teeth and jawbones. Ceramic and carbon coatings are also used in a variety of biomedical devices including prosthetic heart valves. The bonding between hard and soft tissue is being studied to improve such applications. Ceramics are also being used for controlled drug delivery. For example, therapeutic treatment of cancer has been achieved using glass beads doped with radioactive isotopes. In addition, in the drug-delivery arena, rapid prototyping, or 3D printing techniques have been used to fabricate specialized drug-delivery devices. These ceramics are functionally graded structures that can yield complex release profiles in which there is control time, dosage, and even the chemistry of the drug. Ceramics can also be employed as biosensors. Diamond, because of its electrical and chemical properties is a good candidate for integrated sensing materials, and recently, selective biological modification and adsorption has been achieved. In this work, DNA oligonucleotides were covalently bonded to nanocrystalline diamond thin films resulting in an extremely stable, highly selective platform for subsequent surface hybridization processes. This integration of DNA and other biological materials with microelectronics has broad-ranging implications for the development of completely integrated bioelectronic sensing systems.

Conclusion

While these examples testify to the extent and breadth of the research and development in advanced ceramics, there remains much to be understood and accomplished. The ever-expanding variety of analytical tools will provide the technology to further probe the structure and properties of ceramic materials, often at the nanoscale. The blurring of lines between ceramics, biology, and other fields of engineering will most certainly persist requiring that tomorrow's ceramists be cognizant of a broad range of fields and have command of a variety of analytical tools and techniques. Although continually evolving, ceramics will continue to have a large role in the shaping of our society.

Introduction

Although this article presents only a very brief history of polymers, it would be remiss if it did not open by acknowledging that without polymers this encyclopedia would not have been written! Mother Nature, with ingenious dexterity, used “natural” organic polymers such as proteins, polypeptides, carbohydrates, and DNA, to build the structural elements of life itself. Long before there was any fundamental understanding of the macromolecular nature of materials such as cotton, silk, wool, wood, leather, bone, and ivory, humankind found ways to use and modify these materials to produce articles for clothing, utensils, and shelter. One could write books on this subject alone, so in this short history the focus is on how the foundations of our understanding of the nature of polymer materials were laid. In doing so, a lot of important and interesting things have been left out. Accordingly, the focus is on the history of semisynthetic and synthetic polymers, mentioning natural rubber only in passing. (Rubber actually deserves a history of its own and the interested reader is encouraged to consult the sources listed at the end of this review.)

To many people, the birth of polymer science as a discipline starts with Hermann Staudinger and his assertion that materials such as natural rubber are covalently bonded long-chain molecules, as opposed to some sort of colloidal aggregate. Jumps such as this in our understanding of nature do not occur in a vacuum, however. Staudinger was building on a wealth of work by nineteenth-century chemists and entrepreneurs, whose goal was to produce substitutes for various types of increasingly expensive or difficult to obtain natural materials such as ivory and silk.

Early History: Developments in the Nineteenth Century

Perhaps the most enduring images of the industrial revolution of the nineteenth century are those provided by the ironmasters and engineers. One thinks of a world of railways, “dark, satanic mills,” and the social and political consequences of the division of labor and the creation of an urban working class. It is the world according to Charles Dickens, built on iron, steel, coal, and the power of steam. Natural polymers, such as cotton and wool, were, of course, key materials and after Charles Goodyear’s discovery of vulcanization, natural rubber would join them. But, from about the middle to the end of the nineteenth century onward, various synthetic and semisynthetic polymer materials were also introduced and these were to have a profound social and economic impact.

In 1845, common household items such as combs and toothbrushes were often laboriously fashioned from bone or ivory and were thus expensive and unavailable (except in crude wooden forms) to most people. This was to change, although not immediately, with the work of the Swiss chemist, Christian Schönbein. The story (perhaps apocryphal) has it that he used his wife’s apron to wipe up some spilled concentrated nitric and sulfuric acid while conducting experiments in his home. After washing the apron, he put it in front of the fire to dry, upon which it immediately flared brightly and disappeared. Schönbein had discovered guncotton, formed by nitrating the cellulose in the apron. Not only did guncotton have more explosive power than gunpowder, it gave off far less smoke. This was considered a major advance, because it lessened the confusion of the battlefield and generals could now see the people they were slaughtering. Advances in military technology were often spin-off materials and processes that are useful in everyday life, however, and this was to be no exception. Cellulose in its native form is both insoluble and infusible and cannot be cast from solution or molded to make useful objects. However, a French doctor, Louis Menard, found that nitrated cellulose would dissolve in a mixed solvent of alcohol and ether and cast to form a transparent film, called collodion. This was used to dress cuts and wounds. Crucially, it was also found that at levels of nitration of ~13% or less, nitrated cellulose is no longer explosive, although still highly flammable.

Alexander Parkes, a prolific English inventor and true material scientist, had already achieved considerable fame as a metallurgist when he found that the addition of castor oil and camphor to nitrated cellulose lowered its softening temperature. The resulting material, which he modestly called Parkesine, could then be molded. Various objects made from this new material were displayed at the Great Exhibition at the Crystal Palace in 1862, where it won a medal for excellence of product. Parkes seems to have been

unaware of the special role of camphor as a plasticizer, however. In some of his publications he omitted reference to it completely and the commercial exploitation of Parkesine was ultimately a failure. Nevertheless, it marked the beginning of the plastics industry.

This history now shifts across the Atlantic, where the next development came as a direct consequence of a shortage of elephants and rhinoceroses. It is a classic case of a short supply of one material, in this case ivory, providing the impetus for the development of another. The American billiard ball manufacturing company, Phelan and Callendar, offered a prize of \$10 000 (a very large sum in those days) to anyone who could invent a substitute for ivory billiard balls. John Hyatt took up the challenge and chose to experiment with Parkesine. One can speculate that Hyatt might have misspent his youth in pool halls, because he was intrigued by the problem and spent several years of his life working toward a solution. He did not win the prize, but did establish the Albany Billiard Ball Company, which used a mixture of gum shellac and wood pulp to make the bulk of the ball. This was coated with nitrocellulose, which gave this new ball some interesting properties. Hyatt later reported, "We had a letter from a billiard saloon proprietor in Colorado mentioning that occasionally the violent contact of the balls would produce a mild explosion and saying that he did not care so much about it, but that instantly every man in the room pulled a gun." It seems that controlling the degree of nitration remained a problem.

This experience with nitrocellulose prompted Hyatt to investigate its properties in more detail. He eliminated castor oil from his formulations, using only camphor, and, with good old-fashioned Yankee ingenuity, solved the manufacturing problems that had plagued Parkes. He produced a hard material that could be softened by heating to 90°C and called it celluloid. Celluloid was an enormous success. Many common objects that were previously expensive could now be mass-produced cheaply. These ranged from knife handles to false teeth, from combs to that symbol of Victorian rectitude, the stiff celluloid collar. It also provided film for the fledgling movie industry, whose stars became known as the "celluloid kings and queens."

Celluloid was not a true synthetic polymer, of course, but a chemically modified natural polymer. Its central significance to the development of the field was not so much the nature of the objects produced, although these had an important social and economic impact, but the engineering techniques and machines developed to produce these goods. An example is the artificial silk fiber produced by Count Hilaire de Chardonnet, who developed an extrusion process in which a nitrocellulose solution was forced through a small orifice producing a lustrous thread. Unfortunately, nitrocellulose lost none of its incendiary qualities in this process. The workers in Chardonnet's factory quickly dubbed the product "mother-in-law silk" (buy your mother-in-law this nice blouse and stand her in front of the fire), thus revealing an interesting, though morbid, sense of humor. Chardonnet overcame this problem by "denitrating" the fibers by passing them through a solution of aqueous ammonium hydrogen sulfide and, in effect, regenerating cellulose.

There are easier ways to make regenerated cellulose and in the early 1890s Cross, Bevan, and Beadle discovered that cellulose could be rendered soluble by sodium hydroxide and carbon disulfide. A basic solution of cellulose xanthate is formed, which regenerates cellulose upon acidification. Fibers from regenerated cellulose were called rayon, while films were known as cellophane. By the 1930s cellophane was being used to wrap an enormous range of goods, not only to protect them from spoilage, but also because they had customer appeal. A grocery chain reported an increase in sales of an astonishing 2100% in two weeks once their doughnuts were wrapped in cellophane. In a mid-twentieth century poll by the *New York Times*, cellophane was considered to be one of the key discoveries of the century to that date and was even included in a Cole Porter song (You're the Top). The impact of these materials was enormous, but cheaper synthetic polymers have now largely replaced them.

The First Synthetic Plastic

The first truly synthetic polymer materials are the "phenolic resins," originally synthesized by reacting phenol (or, as it was called at the time, carbolic acid, a compound that was, and still is, commonly used as a disinfectant) and formaldehyde (an aqueous solution of which, formalin, had been used in the embalming business for thousands of years). It was actually an Englishman, Arthur Smith, who in 1899 was awarded the first patent for the application of phenol/formaldehyde resins as electrical insulators. But it was Dr. Leo Hendrik Baekeland, a Belgium chemist born in Gent and living in the US, who made the big breakthrough.

Baekeland was an interesting man. He graduated with a Ph.D. degree, "maxima cum laude" and then taught at the University of Gent until 1889. He then left for the US, where he quickly invented Velox, a photographic paper superior to anything else then available. George Eastman, who in 1888 introduced the Kodak camera with the slogan "you press the button, we do the rest," made up his mind to buy Velox and invited Baekeland to Rochester. Baekeland had decided to ask for what was then the very large sum of \$50000, but had it in the back of his mind that he would settle for \$25000. Eastman offered him a million, allowing Baekeland to retire to his laboratory in Yonkers, New York, and look for new chemical worlds to conquer.

Baekeland decided to try and develop a less flammable replacement for shellac, a natural coating derived from the resinous secretions of tiny lac beetles. According to one source, his immediate goal was to develop a wood varnish for bowling alleys, all the rage at that time. Other sources state that Baekeland perceived the growing impact of electricity on everyday life and his goal was to produce a new synthetic insulator. It took roughly 150000 beetles ~6 months to produce enough resin to make one pound of shellac and the demands of the fledgling electrical industry had created a shellac shortage.

Although Baekeland is given the credit for the discovery of phenolic resins, there were significant contributions from many others including Adolf Baeyer, Arthur Smith, Adolf Luft, and James Swinburne. Baekeland's key discovery (made in 1907), one that set him apart from the competition, was that phenolic resins could be made in two parts. In essence, he developed a process where a polycondensation reaction was carried out at an elevated temperature. He then stopped the reaction at an intermediate point by cooling to ambient temperature, where the partially reacted resin solidified. In the second stage, this reasonably stable intermediate

material was placed into a mold and heated under enormous pressure. This transformed the material (by continued polymerization and cross-linking reactions) into a hard, shiny, intractable, relatively brittle solid. Bakelite, as Baekeland called his new material, could be molded and machined; it was hard, relatively strong, lightweight, and resistant to heat. It was the first true synthetic polymer and there was nothing else like it on the face of the planet. It found use not only in electrical fixtures, but also in knife handles, buttons, cameras, radio, and telephone equipment, essentially anything that required a molded part. It was advertised as the "Material of a Thousand Uses." And it was.

The Dawn of Understanding

The polymeric materials discussed so far were developed in a largely "Edisonian" fashion, by trial and error, and in the absence of any fundamental understanding of the macromolecular nature of polymers. In fact, the prevailing view at that time was that materials like silk, cellulose, and natural rubber were colloidal aggregates of small molecules. Not only that, the chemistry of what were then called "high molecular compounds," which could not be purified by crystallization or distillation, was regarded with disdain by the academic chemical community and referred to as "grease chemistry."

It was therefore an act of considerable courage for Hermann Staudinger to decide to devote the bulk of his efforts to these "high molecular compounds." He asserted in lectures and papers (published in the period 1917–1920) that these materials were covalently bonded long-chain molecules. Although Staudinger, at the ripe old age of 39, was a distinguished chemist, holding academic positions at prestigious universities in Karlsruhe, Zurich, and Freiburg, convincing his colleagues was to be no easy matter. For example, Staudinger recollects in *Arbeits Erinnerungen* (Working Memoirs) that he was advised in the 1920s by a famous organic chemist of the day, H Wieland, "My dear chap, give up your ideas on big molecules. There are no organic molecules with a molecular weight of more than 5000. Just clean up your products and they will crystallize and reveal themselves as low molecular weight compounds." In 1925, after giving a lecture at the Zurich Chemical Society, he was attacked by a number of leading scientists and in frustration quoted Martin Luther, "Here I stand and can do no other."

Staudinger could not accept that the physical properties of rubber, proteins, cellulose, and the like could be explained by the idea that they consisted of associations of small molecules held together by some unknown force. (It was speculated at the time that some undiscovered "vital" or life force could be involved.) Staudinger maintained that the atoms in these molecules were connected by covalent chemical bonds, as in low molecular weight materials like benzene, but these molecules just happened to be incredibly large! Despite the apparent reasonableness of this position, the dispute became almost theological in its intensity. Von Baeyer had it right when he pronounced his "Three Stages of a Triumphant Theory": First it is dismissed as untrue; second it is rejected as contrary to religion; and third it is accepted as dogma and every scientist claims to have long appreciated its truth! Staudinger was, of course, correct, and he was belatedly recognized for his achievements in 1953, when he was awarded the Nobel Prize in chemistry. Sometimes you have to outlive your enemies!

Numerous experiments performed by the late 1920s and early 1930s provided accumulating evidence in favor of the existence of macromolecules. Particularly important were Staudinger's work on polyoxymethylenes, where he systematically studied changes in the physical and chemical properties of this polymer and a homologous series of its oligomers; the X-ray diffraction studies of Meyer and Mark, establishing the chain structure of cellulose; and the molecular weight measurement made possible by Svedberg's development of the ultracentrifuge. However, it was the brilliant experimental studies of Wallace Hume Carothers, which were to remove any lingering doubt about the macromolecular, long-chain nature of polymers.

Carothers obtained his doctorate from the University of Illinois, and then took up a teaching position at Harvard. In 1928, Charles Stine persuaded Carothers to leave his teaching post and join the DuPont Company to head a newly formed fundamental research laboratory. He was given wide discretion and he clearly stated at the outset that his goal was to tackle the problem of macromolecules from a chemical approach, by synthesizing compounds of high molecular weight and known constitution. Carothers is best known for the discoveries of nylon and neoprene, but his general contributions to polymer synthesis and polymer structure/property relationships were truly seminal.

Wallace Carothers was probably the first to appreciate the enormous importance of monomer functionality in the production of condensation or step-growth polymers. Amongst many other things Carothers is also credited with categorizing the two major classes of polymerization: condensation or step-growth (which he referred to as "C" type polymerization) and addition (called "A" type). Carothers' crowning glory, one of the major outcomes from his fundamental studies of polymerization, was the discovery of polyamides, or as they are now known universally, nylons. The first major market was ladies' stockings, introduced in the early 1940s. There was a huge demand for this product, which in these days of less formal wear is hard to imagine. Nylon production was co-opted for the war effort after Pearl Harbor was bombed (replacing silk in parachutes and so on), but when nylon stocking production was resumed in 1945 there were actually so-called nylon riots among people lining up to purchase the limited supply. This is a great story, one that would take more space than available here, but it is also a tragic one. Carothers never lived to see the extraordinary success of nylon. The bouts of depression, to which he had long been subject, became increasingly frequent after 1935 and he began to believe he was a failure as a scientist. He left his home in Wilmington, Delaware, on April 28, 1937 and checked into a Philadelphia hotel room, where he swallowed lemon juice laced with potassium cyanide.

The Post 1930s

Following Staudinger and Carothers, the synthesis of polymer materials would become based on chemical principles, rather than empirical trial and error. It was now understood what types of functional groups could react to form polymers and chemists set about making them. Nevertheless, it took years of effort by many scientists to achieve a firm understanding of the details of reaction mechanisms and their kinetics. For example, industrial scale polymerization of vinyl monomers in Germany by what became recognized as a free radical mechanism was in early work (late 1920s) initiated by exposure to sunlight. Initiation also played a crucial role in the development of a high-pressure process for the polymerization of ethylene by Fawcett and Gibson at ICI (Imperial Chemical Industries) in England in the 1930s. While trying to react benzaldehyde with ethylene at high pressure, a waxy solid was formed which they recognized to be a polymer of ethylene. A subsequent experiment blew up the apparatus and ICI banned high-pressure studies until stronger reaction vessels could be constructed. Fawcett left to join Carothers' group in America, but Perrin continued work in secret after normal working hours, risking both his life and his job. By 1936, it was recognized that small amounts of oxygen could initiate the reaction and by 1939, production of significant quantities was achieved. This turned out to be crucial for the war effort. Because polyethylene turned out to have an extremely low dielectric loss, it was ideal for radar cable insulation. As Robert Wattson Watts, the British inventor of radar, stated, "The availability of polyethylene transformed the design, production, installation and maintenance of airborne radar from the most insoluble to the comfortably manageable. And so, polyethylene played an indispensable part in the long series of victories in the air, on the sea and the land, which were made possible by radar."

By 1950, significant advances in understanding free radical polymerization, the nature of copolymerization, emulsion polymerization, etc., had been achieved. At the same time, the period between the first and second World Wars had seen the introduction of a number of important condensation polymers, which included not only nylon, but also the polyurethanes. Otto Bayer, who just happened to have the same name as the large German company for whom he worked, became head of the Central Scientific Laboratory at the ripe old age of 31. He was aware of the work of Staudinger and Carothers and reasoned that a superior "condensation" polymerization would be one where a small molecule (such as water) was not split off. He had worked on isocyanate chemistry and perceived that diisocyanates might form the basis for making such polymers. Synthesizing diisocyanates is hard and dangerous chemistry and one of Bayer's closest colleagues remarked, "If you had ever tried to make a monoisocyanate, you would not have come up with the mad idea of trying to produce diisocyanates. The reaction of phosgene on diamines would result in almost anything except diisocyanate, and would probably be thoroughly unstable, anyway." Others added, "It will explode!" This is another great story, which too cannot be told properly for want of space, but needless to say, Bayer succeeded.

Although some addition polymerizations involving catalysts and ionic initiators were performed between the two World Wars, it was not until the early 1950s that things really took off, when catalysts for the low pressure polymerization of ethylene were discovered, independently and almost simultaneously in the early 1950s, by Karl Ziegler in Germany and Robert Banks and Paul Hogan at the Phillips Petroleum company in the USA. These were not the only scientists involved, as workers at Standard Oil of Indiana were pursuing similar goals, while Giulio Natta, a Professor at the Politecnico di Milano, had become interested in the field after he heard a lecture given by Ziegler. Natta had sent some of his collaborators to work in Ziegler's laboratory to learn the art and craft of the technique and upon their return, Natta set out to synthesize polypropylene, which could not be made free radically. They succeeded and filed for a patent just days before Ziegler's group, who by then had also succeeded in polymerizing propylene. Although Ziegler and Natta were jointly awarded the 1963 Nobel Prize in chemistry, they were no longer speaking to one another. Polypropylene also became the subject of one of the longest patent cases in history.

There is much more to this story, and the history of the development of many other major polymers and classes of polymers is equally fascinating. But although a history of polymer materials naturally focuses on how these materials were discovered and synthesized, an understanding of the physics and physical chemistry of these materials was equally important. It was Carothers, looking for a physical chemist to join his group, who hired the newly graduated Paul Flory in 1934. Carothers encouraged Flory to carry out mathematical investigations of polymerization and the subsequent impact that Flory was to have on the field of polymer science is difficult to overstate. Flory's book, *Principles of Polymer Chemistry*, is still a classic 50 years after publication and essential reading for anyone starting out in this field. In 1974, he was awarded the Nobel Prize in chemistry for his fundamental achievements, both theoretical and experimental, in the physical chemistry of macromolecules. While many other notable scientists have contributed to the theory of polymers, Pierre-Gilles de Gennes has a knack for seeing commonalities in wildly different physical systems and then reducing these observations to simple scaling arguments. His book, *Scaling Concepts in Polymer Physics*, is also a required reading for aspiring polymer physicists. In 1991, his peers recognized de Gennes' accomplishments and he was awarded the Nobel Prize in physics.

Final Words

There is much that has been omitted and many great scientists have been slighted by these omissions. The authors can only suggest that if they have sparked any interest in the reader that he or she refers to the references cited below.

Introduction

The expression “neutron scattering” commonly refers to the study of condensed or gaseous matter by observing the scattering of a neutron beam from a sample of the material in question. If the energy of the neutrons in the beam is much higher than the typical energy of the interactions of the atoms in the sample matter (e.g., the energy of chemical binding within constituent molecules), the collision of neutrons with the nuclei of the atoms depends only on the properties of the individual nuclei and carries no information on the properties of the material. Thus, the subject matter of this article is the history of using low-energy (typically less than 1 eV) neutron radiation for exploring what happens inside common materials.

The idea that neutrons can reveal precious information about the structure of such materials – solids, liquids, and to some extent also gases – was born shortly after neutrons were discovered by Chadwick in 1932. Practical neutron scattering started as a parasitic activity on research reactors built in the 1940s for developing nuclear energy. Since the 1960s, several facilities around the world have been specifically designed, built, and dedicated primarily for neutron scattering research to serve by the end of the twentieth century a worldwide community of about 7000 users of neutrons as one of their tools in the study of a vast variety of topics in condensed matter research, including physics, chemistry, biology, geology, archeology, and engineering. In 1994, Shull and Brockhouse, the two outstanding pioneers of neutron scattering in the 1950s, were awarded the Nobel prize in physics for discovering how the neutrons show “where the atoms are and what they do.”

Establishing the Conceptual Foundations

As early as in 1936, Elsasser suggested that neutrons move as waves through matter and as these waves scatter on the nuclei of individual atoms, interference may occur between the partial waves scattered from different atoms, as was known since the 1910s for X-rays. This was demonstrated in the same year by observing the strong reflection of neutrons on large magnesium oxide single crystals. In this respect, the fundamental difference that neutrons scatter on the nuclei and X-rays on the electron cloud surrounding these nuclei in the atoms was of no principal consequence.

In 1936, Bloch also made a visionary proposition, which in contrast had no analogy in X-rays. Due to the fact that the neutron possesses a magnetic moment, Bloch realized that they could also feel the magnetic fields inside magnetic materials. The magnitude of the neutron magnetic moment is $\mu_n = 1.04 \times 10^{-3} \mu_B$, where the Bohr magneton μ_B essentially equals the magnetic moment of a free electron. The internal average magnetic field (induction) inside ferromagnetic iron is $B = 2.2 \text{ T}$ and the energy of the Zeemann interaction in this field $E = -\mu_n B = 1.32 \times 10^{-7} \text{ eV}$ acts as a potential on the neutron (attractive if the neutron magnetic moment is parallel to the field B , and repulsive for antiparallel direction), which can measurably deflect a neutron beam. Bloch pointed out that, since the internal magnetic field distribution in a magnetic material is not homogeneous but shows strong maxima centered around the position of the nuclei, the internal magnetic field distribution shows a periodic structure in crystalline magnets and therefore with neutrons, not only the atomic structure determines the Bragg diffraction peaks well known for X-rays, but there is also a contribution from the magnetism of the atoms.

It is of particular historical interest that while Bloch’s visionary recognition of the great potential of neutron scattering in the study of magnetic materials proved to be of outstanding importance in the investigation of magnetic phenomena, for example, the study of high-temperature superconductors in recent decades, he proposed a mathematical expression, which was debated for nearly 15 years and finally proved to be wrong. This controversy reflected a fundamental ambiguity of electromagnetic theory, which could finally be settled by the neutron reflectivity experiments of Hughes and Burgoyne (1951). In electromagnetic theory, two fields are associated with magnetic materials: the so-called magnetic field H and magnetic induction B . These two are equal outside

the magnetized matter, the only place where one could place a measuring device. This was going to change with the neutrons: as neutral particles, neutrons interact weakly with most materials and can penetrate deep inside heavy objects (e.g., many centimeters in steel), and as a quantum mechanical particle wave, they can theoretically spread over an unlimited volume of the sample. So magnetism could, for the first time, be observed inside magnetic materials, with the measuring probe, the neutron occupying the same space as the sample magnetic material. Although the details did not appear to be so clear at that time, Bloch's 1936 theory implied that the interaction between the neutron magnetic moment and magnetism corresponds everywhere, including the inside of matter, to the energy

$$E = -\mu_n H \quad [1]$$

whereas the different formulas proposed by Schwinger in 1937 were shown to correspond to the general assumption

$$E = -\mu_n B \quad [2]$$

The experiments of Hughes and Burgy, which could only be done when a few years after World War II intense neutron beams became available for research at nuclear reactors, settled the ambiguity in favor of eqn [2]. To overcome a repulsive energy barrier of ~ 100 meV corresponding to the magnetic induction B inside iron for the neutrons with magnetic moment opposite to the magnetization of the sample, the neutrons needed to have at least 5 m s^{-1} velocity perpendicular to the surface. Below this value, the neutron beam is totally reflected. Thus for typical velocities of the neutron beams available from reactors in the range of 2000 m s^{-1} , the range of total reflection will extend up to grazing incident angles of $\sim 0.1^\circ$ (the so-called critical angle). Hughes and Burgy determined the potential energy by the observation of the critical angle in magnetized Fe films. Their conclusion that $E = -\mu_n B$ was shown to imply that the magnetic moment of the neutron should be considered as a microscopic Amperian current loop, and not as a dipole built by opposing charges.

Actually, the total potential energy at a surface is the sum of the magnetic and nuclear contributions, where the latter designates the average potential presented by the interaction between the neutrons and the nuclei of the atoms in the sample, and the detailed shape of the reflectivity curve above the critical angle of total reflection depends on the detailed profile of the potential, which can show considerable structure, for example, in surfaces consisting of a number of thin layers. Decades after the pioneering work of Hughes and Burgy, neutron reflectivity became a widely-used tool for the study of surfaces and thin film structures, in particular following Felcher's important study of the penetration depth of magnetic fields at the surface of superconductors in 1979.

Neutron Diffraction

Practical neutron scattering work started more than 10 years after the theoretical suggestions by Elsasser and Bloch, when nuclear fission reactors became available for research. The energy of fission neutrons is very high ($\sim \text{MeV}$), and they first need to be slowed down before they can be used in neutron scattering work. This was achieved by the thermalization process, in which neutrons are made to collide randomly with light, small absorbing nuclei (originally C in graphite) whereby after a few collisions a neutron gas with a temperature close to the temperature of the moderator is produced. The energy of the neutron emerging from a moderator

$$E = mv^2/2 \quad [3]$$

(where m is the neutron mass, $m = 1.67 \times 10^{-24} \text{ g}$) is on average close to the thermal energy $k_B T$ at the temperature of the moderator, that is, 25 meV at room temperature. The corresponding neutron velocity $v = 2200 \text{ m s}^{-1}$ is equivalent in quantum wave mechanics to a wavelength of $\lambda = 0.18 \text{ nm}$, as given by the de Broglie relation

$$h/\lambda = mv \quad [4]$$

where h is Planck's constant. This wavelength is comparable to the 0.154 nm of the $K\alpha$ X-ray radiation of copper, mostly used for crystallographic studies at that time. However, the wavelength distribution in the neutron beam extracted from the moderator was very broad and to build the first neutron diffractometer in 1948, Shull and Wollan at Oak Ridge used a monochromator single crystal to obtain a neutron beam with a well-defined wavelength. The next step was to measure the neutron scattering power for a large number of atomic nuclei by studying the neutron diffraction pattern for many well-known crystals. It turned out that this power changes rather randomly from one nucleus to the other, and, in particular, in neutron diffraction one can see the contributions of light elements (e.g., hydrogen) also in the presence of much heavier ones. This is an important contrast of great practical utility to X-ray diffraction, where heavy elements in the crystals tend to mask the lighter ones.

The first decisive discovery by using neutron scattering was made by Shull and Smart in 1949 at Oak Ridge: they found a new Bragg peak in the neutron diffraction pattern of MnO at low temperatures, which could not be seen in X-ray studies (Figure 1). It was the first experimental evidence for antiferromagnetism, showing that the magnetic moments of the Mn atoms are aligned parallel for every second atom in certain lines and antiparallel for the atoms in-between. This breakthrough established neutron scattering as the preferred tool for the study of magnetism on the atomic scale. It is worth noting that this seminal discovery was made before the controversy on the coupling between neutron and magnetism had been settled. However, the existence of Bragg peaks in a sample without preferred magnetic orientation did not depend on the exact form of the interaction.

Figure 1 The first experimental evidence for antiferromagnetism by neutron diffraction. (Shull CG and Smart JS (1949) *Physical Review* 76: 1256.)

Neutron diffraction experiments can not only reveal crystalline long-range order, but also much less regular arrangements of atoms. In such cases the Bragg peaks are replaced by broad “diffuse scattering” structures in the scattering diagram (such as in the lower curve in Figure 1 around 11° scattering angle), which carry information on a large variety of phenomena, such as the way in which one atom is surrounded by neighbors in a liquid or the size and arrangement of precipitates in an alloy. Information on larger structures shows up at smaller scattering angles, which gradually led (from the late 1950s) to the development of small angle neutron scattering (SANS) as a very special form of neutron diffraction.

Inelastic Scattering

The atoms and molecules inside condensed matter move around locally with energies comparable to $k_B T$. This leads to the appearance of the so-called inelastic scattering processes, in which the energy of the scattered particle is changed by an exchange with the kinetic energy of the atoms. Since for ordinary temperatures, the energy of the thermal motion of atoms in the sample is comparable to the energy of the neutrons from ambient moderators, the energy change of the neutron in the corresponding inelastic scattering processes can be quite substantial, and therefore readily measurable. In contrast, the quanta of X-rays with wavelength convenient for scattering work on condensed matter (i.e., in the range of atomic distances in the sample) are very high, and inelastic processes due to motion of atoms are difficult to observe. For example, the energy of the above-mentioned $K\alpha$ X-ray radiation is 7.8 keV, ~ 300000 times higher than energy of neutrons with similar wavelength. Since the early 1950s, several research groups have demonstrated the existence of such inelastic processes in neutron scattering. The decisive breakthrough came from Brockhouse at Chalk River by the introduction of triple-axis-spectroscopy in 1958, a technique to put these studies on firm grounds adequate for theoretical interpretation.

In 1954 van Hove developed a general theoretical framework for neutron (and other) scattering experiments in condensed matter. The particular significance of the van Hove theory for neutrons was that since the neutron interaction with most condensed matter sample is weak (again a very important difference from X-rays), this theory applies with great precision in most cases. The theory allows us to calculate the probability for the neutron to scatter from an initial state with velocity v_i to a final state with velocity v_f for any complete model of the behavior of the sample, including both the arrangement of the atoms in space and their motion, for example, vibrations around steady equilibrium positions in solids, or the microscopic motion leading to fluidity in liquids. The van Hove scattering function $S(q, E)$ is a function of two parameters, the momentum transfer vector q and the energy transfer E , which are defined in terms of the initial and final neutron velocities as follows:

$$q = mv_f/\hbar - mv_i/\hbar \text{ and } E = mv_f^2/2 - mv_i^2/2 \quad [5]$$

Figure 2 The basic layout of triple-axis spectrometers. The single crystals X1 and X2 are the monochromator and analyzer, respectively, and S is the sample. (Brockhouse BN and Stewart AT (1958) *Reviews of Modern Physics* 30: 236.)

where $\hbar = h/2\pi$ and v_f and v_i are the absolute values of the velocity vectors $\mathbf{v}_f$ and $\mathbf{v}_i$. The triple-axis technique of Brockhouse allows us to select a well-defined pair of values $\mathbf{q}$ and E . This was a real breakthrough, since the computing power in theoretical calculations was rather limited at that time and model calculations such as the energy dispersion relation of a phonon or magnon excitation branch α in single crystals, $E_\alpha(\mathbf{q})$, could only be calculated for special momentum transfer vectors $\mathbf{q}$ in highly symmetric directions in the crystals.

The principle of triple-axis spectroscopy is very simple (Figure 2): both the initial and final neutron velocities can be selected with great flexibility, by a monochromator and an analyzer crystal, in order to fulfill both the equations in [5] for a wide range of desired values of the four parameters represented by the vector $\mathbf{q}$ and the scalar E . This requires calculating the three scattering angles for the monochromator, sample and analyzer, and automatically setting the spectrometer and the orientation of these three crystals in the right configuration. This was the key technical innovation behind the introduction of triple-axis spectroscopy. The most common mode of operation is to design scans of one of the above-mentioned four parameters, for example, in “constant $\mathbf{q}$ ” scans a set of data points are taken at different E values, while the vector $\mathbf{q}$ is kept constant with respect to the sample. The diffractometer, or “two-axis” spectrometer, used by Shull and collaborators differs from the one in Figure 2 only by the lack of the analyzer crystal: the detector only records the distribution of the scattered neutrons as a function of the scattering angle, without analyzing the magnitude of their velocity. This is done under the tacit and frequently valid assumption that the inelastic scattering is weak compared to the elastic one with $v_f = v_i$, and therefore it can be neglected.

An alternative approach to inelastic scattering is to produce pulses of neutrons with a constant initial velocity v_i and determine the final velocity vector $\mathbf{v}_f$ by recording the time of arrival of the neutrons at the immobile detector banks surrounding the sample, where the position of each detector corresponds to a given scattering angle. A 2–4 m flight path between the sample and the detectors is sufficient to determine the final neutron velocities with a reasonable precision. This “time-of-flight” (TOF) method was developed at several places in incremental steps parallel to the triple-axis technique, including early work with mechanical choppers to produce neutron pulses by Jacrot at Saclay. TOF techniques are most often used for isotropic samples, for example, liquids, where only the absolute value of $\mathbf{q}$ matters, not its direction compared to the orientation of the sample. Figure 3 shows the elementary excitation spectrum of superfluid ^4He below 2.17 K. The observation of the minimum in the $E(\mathbf{q})$ dispersion relation at $q = 19.3 \text{ nm}^{-1}$ provided direct evidence for the theories of Landau and Feynman.

Polarized Neutrons

The van Hove scattering function as given above applies to the simplified situation of neglecting the neutron magnetic moment. While the initial and final states of the neutrons are only fully characterized by not only keeping track of the velocity but also of the direction of the magnetic moment vector $\boldsymbol{\mu}$ (or that of the associated neutron spin with $s=1/2$), only the velocity has been considered so far. This corresponds to the real experimental situation in “unpolarized neutron scattering,” where $\boldsymbol{\mu}$ is randomly oriented in the incoming beam and its orientation is not determined in the scattered beam. In the most general case, one needs to define both the initial and final states by the five parameters $(v_i, \boldsymbol{\mu}_i)$ and $(v_f, \boldsymbol{\mu}_f)$, respectively (vector $\boldsymbol{\mu}$ represents only two free parameters, since its magnitude is given). Thus, the van Hove scattering function will take the form $S_{\alpha,\beta}(\mathbf{q}, E)$, describing the

Figure 3 The dispersion relation of elementary excitations in superfluid ^4He observed by inelastic neutron scattering. (Yarnell JL, Arnold GA, Bendt PJ, and Kerr EC (1958) *Physical Review Letters* 1: 9.)

scattering probability from an initial neutron state with magnetic moment direction α to a final one with magnetic moment direction β .

The two basic methods used nearly exclusively until now to produce polarized neutron beams were also discovered early on, in 1951. One of them is essentially the reflection of neutrons on magnetized mirrors used by Hughes and Burgoyne to identify the interaction of neutrons with magnetic fields, as discussed above. The potential in eqn [2] for the internal B field in the ferromagnetic mirror (Fe or Co or their alloys) makes the critical angle of total reflection different for neutrons with magnetic moment oriented parallel or antiparallel to the direction of the field magnetizing the mirror. Thus, in the angular range between these two critical angles (referred to as “spin up” and “spin down” critical angles), the reflectivity will be substantially larger for one direction of the neutron magnetic moment, and the mirror selects from the originally unpolarized beam a preferred magnetic moment (or spin) direction. This technique is simple and inexpensive; it has the disadvantage though that the difference between the “up” and “down” critical angles is rather small, and therefore it can only select a rather limited fraction of the neutrons emerging from the reactor in all directions. In 1976 Mezei introduced the “supermirrors” to enhance the angular range of efficient polarizing neutron mirrors by complementing the range of total reflection by a range of nearly total reflection by interference on a stack of up to ~ 500 thin layers of alternating magnetic and nonmagnetic layers with carefully designed sequence of thicknesses between ~ 3 and 50 nm. Most mirror-based neutron polarizers in operation today use supermirrors.

The other basic method of polarizing neutrons is to use an adequate Bragg reflection from a single crystal. In ferromagnetic materials, unlike the case of antiferromagnets shown in Figure 1, the magnetism of the atoms leads to a magnetic contribution to the Bragg peaks corresponding to the atomic crystal structure. This makes the intensity of the reflection dependent on the relative direction of the neutron magnetic moment with respect to the magnetic field polarizing the sample. For a few special Bragg peaks in various materials, the intensity of the reflection can be two orders of magnitude different for neutron spins parallel or antiparallel to the crystal magnetization. This was first observed by Shull in 1950 for a reflection in magnetite, Fe_3O_4 . He also pointed out that by observing the effect of the beam polarization on the scattered beam intensity in a magnetized sample one can increase the sensitivity of neutron scattering experiments in the study of weak signals from magnetic samples by orders of magnitude, for example, for detecting ordered magnetic moments in the range of $10^{-3} \mu_B$ per atom.

Polarization Analysis

For the unambiguous identification of the magnetic signals in complex magnets or inelastic scattering, in particular in paramagnetic or antiferromagnetic samples which cannot be magnetized in moderate fields, one needs to resort to polarization analysis. Here the scattered beam intensity might not depend on the initial beam polarization; instead, the scattered beam polarization needs to be determined. Experimentally this can be achieved by replacing both the monochromator and analyzer crystals on a triple-axis spectrometer by a crystal with a polarizing reflection and control the beam polarization between the polarizer and analyzer crystals, for example, by maintaining it in a given direction or “flipping” it. Several researchers have made important steps in this direction, in particular, Drabkin and collaborators at Gatchina. In 1969, Koehler, Moon, and Riste established the first experimental evidence for the characteristic polarization behavior of different scattering processes. In the approach, they established (what is now called

“one-dimensional polarization analysis”) that both the initial and final beam polarization can be either parallel (+ or “up”) or antiparallel (– or “down”) to the field direction on the sample. Thus, the choice of α and β directions in the above general form of the van Hove scattering function reduces to the combinations: “++” for the probability of scattering from the + neutron spin direction to the same one, $S_{++}(q, E)$, and similarly “--,” “+-,” and “-+.” The first two processes are without change of spin direction (“non-spin flip”) and the last two ones involve the reversal of the neutron spin (“spin flip”). Later developments (primarily at Delft, Gatchina, and ILL, Grenoble) led to generalized or vectorial (3D) polarization analysis (or polarimetry), where α and β can be arbitrary directions. A historically important example of complex vectorial behavior of the scattered beam polarization is the early prediction by Halpern and Johnson in 1942 for the magnetic scattering in paramagnetic samples, giving the direction of the scattered beam polarization P_f (which is defined as the average of the individual neutron magnetic moment directions in the beam) as a function of the initial one P_i and the unit vector parallel to the momentum transfer $\hat{u} = \mathbf{q}/q$ as

$$P_f = -\hat{u}(P_i \hat{u})$$

Special cases of this relation (when P_i and $\hat{u}$ are either parallel or perpendicular) have been demonstrated in 1969 by Koehler, Moon, and Riste, while the full vectorial relation could only be verified later.

Neutron Spin Echo

The generic scheme of neutron scattering experiments consisting of preparation of an initial beam with more or less well-defined v_i and analysis of the final distribution of v_f , as it is common, for example, for triple axis (Figure 2), TOF, and other techniques. It implies that for the observation of small changes, the initial and final velocities must be very well defined, that is, very few neutrons will be selected from a broad distribution in direction and absolute velocity. The neutron spin echo method, invented by Mezei in Budapest (1972) uses a drastically different paradigm. It consists in making each neutron effectively carry its own stopwatch and, using this, compare a selected component of v_i with another component of v_f . Thus, the determination of minute relative changes of the neutron energy in the 10^{-6} range can be measured at a rough monochromaticity of 10–20%. The Larmor precession of the magnetic moment of each neutron in well-defined magnetic fields serves as the clock attached to each neutron (Figure 4). Neutron spin echo thus allows to extend the upper limit of time domain 10^{-14} – 10^{-9} s where atomic motions can be studied by methods of inelastic neutron scattering up to 10^{-6} s, making accessible many processes in macromolecular systems.

Steady-State and Pulsed Neutron Sources

The most recent revolution in neutron scattering is driven by the evolution of the methods of producing neutron beams. As we have seen, the need to select neutron beams with a more or less well-defined initial velocity v_i by some monochromator implies that one should throw away the vast majority of the neutrons produced with a broad velocity distribution and emitted in all directions by the

Figure 4 The layout of a neutron spin echo spectrometer. (Mezei F (ed.) (1980) *Neutron Spin Echo*. Berlin: Springer.)

Figure 5 Evolution of the flux of neutron sources available for neutron scattering over the past decades at different facilities. The flux is defined here as the number of neutrons crossing unit area of the surface of the ambient temperature moderator in unit time. It is measured in units of $\text{cm}^{-2} \text{s}^{-1}$. For pulsed sources, the flux at the peak of the pulses is shown.

moderators. Cutting out pulses of the beam by a mechanical chopper was found early on as an efficient way to select their velocity, for example, 0.2 ms pulses every 10 ms provide a suitable monochromatic beam for TOF spectroscopy over a typical flight path of 20 m. Such a monochromator only needs neutrons for a short time every 10 ms; for the rest the source could be switched off to save costs and heat production, the latter being the ultimate technical limitation. It is difficult but not impossible to operate reactors in a pulsed fashion, and this approach has been pioneered at Dubna near Moscow since the 1960s. The IBR-2 pulsed reactor source at Dubna today achieves 1500 MW instantaneous power (heat production) when switched on for about 0.3 ms, while steady-state reactors cannot practically surpass 100 MW.

Neutrons can also be produced by accelerators, that can easily operate in a pulsed mode. This approach was first pioneered by Tohoku University in the 1960s using electrons. The most efficient accelerator-based neutron production technique, the so-called “spallation,” was established in Argonne near Chicago by Carpenter and collaborators in the 1970s. Here a pulsed proton beam is accelerated to typically 1 GeV energy, and each proton absorbed in a heavy-metal target sets free ~ 30 neutrons in a series of collisions with the nuclei. Thus, the energy needed per neutron produced (~ 30 MeV) is much less than the ~ 190 MeV heat accompanying the birth of a recoverable neutron in the fission process in reactors. The great new potential offered by high-power spallation sources, as illustrated in Figure 5 by the peak instantaneous neutron flux they can produce during the pulse, is based on this double gain of efficiency: less heat is produced per usable neutron and the source is switched off for much of the time when no neutrons are needed. Although, by itself, the peak flux of a pulsed source compared to the time average flux of a steady-state reactor does not fully characterize its performance in all applications, the great potential of progress with future multi-MW spallation sources is well illustrated in Figure 5.

Neutron Optics

While source performance has not improved much since the 1950s in terms of number of neutrons produced, the intensity of neutron beams available in scattering experiments has steadily increased over the same period of time, in particular by the advent of Institut-Laue-Langevin (ILL) in Grenoble, the most powerful neutron scattering facility in the world operated through a European collaboration. At the 58 MW fission reactor at ILL three different moderator temperatures 25, 300, and 2000 K are available in order to provide the best-adapted neutron spectrum for the various instruments, and that has become a standard for more recent research reactors. The art of “neutron optics,” the development of increasingly efficient components for transporting, shaping, monochromatizing, and analyzing neutron beams has also steadily progressed. One of the key inventions was the introduction of neutron guides by Maier-Leibnitz in München in the early 1960s. Neutron guides are rectangular tubes with cross-section up to 100–200 cm^2 with the internal walls made of totally reflecting mirrors (usually highly polished glass coated with an adequate metallic layer). These guides can transport intense neutron beams over large distances with minimal losses with a beam divergence limited

by the critical angle of total reflection (typically a few tenths of a degree). More recently, the divergence, and hence the intensity of the beam transported in the guides, is enhanced by using supermirror coating. The early single crystal monochromators are replaced by arrays of single crystals focusing the beam on the sample, and an increasingly larger fraction of the scattered neutrons is captured by using large position-sensitive area detectors. The combination of continuously advancing neutron optics with the enhanced neutron flux of the next-generation neutron sources means that the power of neutron scattering methods is increasing much faster than indicated by the trendline in [Figure 5](#) for spallation sources.

Introduction

A ceramic is defined as a nonmetallic inorganic solid, but in a narrow sense it is a massive solid obtained by the heat treatment process of inorganic powders.

Ceramics have a long history. One of the first materials used by humans was a stone implement. Obsidian in composition, such a material can be classified as being glassy. Similarly, porcelain and earthenware also have a long history. The same can be said of glass too; human beings produced glassy solids in 3000 BC. Ceramic powder was also used as an adhesive at the time of the construction of the pyramids.

Ceramics are classified, from the viewpoint of structure, as: (1) single crystal, (2) sintering object, (3) glass, and (4) powder.

1. The technology to produce single crystals artificially is difficult; moreover, it is not suitable for mass production. Commercial ceramic products in the form of single crystals are, therefore, rather new historically. At present, some of the single crystals such as a quartz oscillation unit and an optical crystal are of much importance, because it is impossible to obtain the desired properties by using materials other than single crystals.
2. Sintered bodies are obtained by a forming process where starting powders are pressurized and the massive solid is obtained by subsequent heat treatment. Although earthenware was the origin of this technique, ceramics with various functionalities were developed.
3. Glass is a material obtained through a melting state by heating starting raw powders at a high enough temperature. Since the composition of common glasses was similar to that of earth, it was made artificially as early as in 3000 BC. However, these early glasses were not transparent. Although glass as a transparent material was developed later, it was only in the twentieth century that the technology of manufacturing sheets of glass with larger area became available.
4. Powders have been used from the BC period by grinding natural ores. The history of pigments also goes back a long way. Powder today means such materials as can be used in making high-performance sintered ceramic bodies. Original materials for ceramics were natural minerals, especially silicates. Clay, which is a natural silica mineral and very suitable for the production of porcelains, was the primary raw material for a long time. It is, therefore, understandable that the industry which used clay emerged first. The ceramic industry showed a marked progress after materials other than silicates came into use. Alumina is the first example and titanium oxide as a dielectric followed in industrial use. These simple oxides offered an easy control of the properties of their powders, suggesting that substances with easy handling became raw materials for practical use.

Silicate industries have also undergone constant development. The wall thickness of ordinary china used for tableware is ~ 1 mm; ~ 50 μm thick silicate ceramics are manufactured in large quantities as catalyst carriers for cars (in the absence of this technology, automobiles would perhaps be contributing to air pollution at levels even higher than they do now).

As a next step, complex oxides constituted the mainstream of the practical use of ceramics. The first generation of complex oxide ceramics are barium titanates and ferrites. These substances came to be used, due to a great deal of development in the management of purity, fine-tuning of composition, surface modification, etc. For example, the control of grain boundaries is one of the most important parameters that determines the total characteristics of a ceramic material. New types of ceramic heaters, which are capable of self-control of temperature with a composition of barium titanates, were developed and used. These are characterized by controlled grain boundaries and the so-called positive temperature coefficient (PTC).

Most industrial applications of ceramics exploit the characteristics of the substrates on the one hand and the electronic or ionic properties of their constituents on the other.

Nowadays, the most useful example of functional ceramics are lead zirconium titanates (PZTs). For instance, cellular phone designs are materialized by using these piezoelectric ceramics. Barium titanates and ferrites, sometimes called electronic ceramics, are extensively used in the electronics industry. This is because the electronic properties play a crucial role in determining the function of these ceramics.

Simultaneously, materials using the ionic properties of ceramics have also emerged and are used practically. The purification of the exhaust gas of a car is attained due to the use of zirconium oxide ceramics as an oxygen sensor, thus utilizing the ionic conductivity of oxide ions. It is called a solid electrolyte because the substance has conductivity due to an ionic motion within a solid. One of the notable examples is beta alumina, which is now used as an electrolyte for a Na-S battery, a large-sized rechargeable battery for load leveling of electric power.

A compositional survey of the possible properties of oxides containing two or three metals has already been conducted. Although additive agents are used to promote sintering or optimization of properties, compounds which principally contain more than four kinds of metals are seldom examined. In this unexplored area, a new category of ceramic materials has emerged, that is, superconducting ceramics.

It is to be noted that the most important characteristic of ceramics is their tolerance to high temperature. For many years, oxides have been used as refractory materials. It is quite clear that "refraction" supports the basic technology in the metal-refining industry. By extending the function of an oxide as a high-temperature material to the extreme, its application in the area of energy production etc., can be expected. However, it was not oxides, but nitrides and carbides, which attracted attention as such materials in the 1980s. As a result, a ceramic turbocharger was developed for automobiles. Although non-water-cooled engines made from ceramics were proposed to be used, this has not yet been realized.

The glass industry at present is very large in scale. This is one of the several reasons for natural silica to be the major raw material in the industry. An example of the application of glass, which uses transparency to its extreme, is the optical fiber. An optical fiber is made from very high purity silica although it includes a very small quantity of additives to control the contour of refractivity.

The composition of the often used glasses resembles that of sheet glass or bottles. The insulated film used in semiconductor devices is also glassy. Although only glassy material with a simple composition can be used in device processes, one can expect new compositions to find future applications.

Cement is a material which has been used in large quantities for a long time. Of course, it is also a product of the silicate industries. The use of a material in such large quantities is bound to pose a problem of depletion of resources, sooner or later.

History of Development of Ceramics

In the preceding section, an outline of ceramics was given from the historical point of view. The present section selects some ceramics as examples to consider the development process in more detail.

Large-sized Insulator and Ceramic Carrier

The largest ceramic (1.2 m $\varnothing \times$ 12 m length) ever made was the insulator for 1000 kV power transmission. In consideration of it being corrosion-proof and earthquake-resistant, it had a special form of a bamboo hat and was made of large-sized porcelain with a thick wall.

The catalyst system was established as a primary means of automobile exhaust gas purification. Although started in the form of pellets, the monolithic honeycomb-type catalyst carrier was developed in 1976. This type of catalyst opened up the possibility of stricter emission control of automobiles.

Cordierite, with a composition of $2\text{MgO} \cdot \text{Al}_2\text{O}_3 \cdot 5\text{SiO}_2$, was used because of excellent heat resistance due to a low expansion coefficient. In the initial stage, the number of cells was $\sim 200/\text{square inches}$ (1 inch = 2.54 cm) but later reached 900 square inches, and the wall thickness decreased from 12 mil (1 mil = 0.0254 mm) to 2 mil.

Alumina (Aluminum Oxide) and Substrate Material

Some aluminum oxides have been used for many years as refractory materials. Examples range from highly pure alumina crucibles to low-purity alumina pipes or plates for low-heat-resistance applications. Their application as an insulator for spark plugs was developed in 1931, and alumina started being used in automobile and electronics industries.

The decisive extensive use of ceramic materials in electronic industries occurs in the form of substrate materials used as a part of large-scale integrated circuits. Alumina substrates for electronic circuits cover a wide range of products, such as those made by the thick-film process, the thin-film process, and multilayer-type circuit boards. Alumina powders with purity higher than 99.5%, with 0.2% of magnesium oxide as additives, are generally used to give a flat and smooth surface, which is excellent for use as substrates.

The multilayer aluminum circuit board was first developed by IBM for the CPU used in the 308 X series mainframe computers. The CPU was $90 \times 90 \text{ mm}^2$ in size and the number of layers was 33. It was evaluated that this circuit board had superior properties

both in the delay time of signal propagation and heat dissipation. Silver, gold, copper, etc., were used as conductive materials for wiring.

Because of the success of the alumina circuit board for the CPU, other substrate materials with higher heat dissipation capability, such as in the AlN and SiC boards, were investigated. Since AlN and SiC have simple crystal structures, both materials have excellent thermal conductivity, provided the grain boundaries are controlled. Since AlN is an insulator, it is only necessary to control the grain boundaries to obtain a high heat conduction, but since SiC has electronic conductivity, it is inevitable to control the grain boundaries so that it is electrically insulating. It was found that the addition of BeO as a sintering agent changed ceramics to insulating substrates.

Although ceramic substrates for large-scale integrated circuits were excellent in performance, the production cost was a prohibitive factor for use of this product. The semiconductor packaging process was changed, and it was found that even plastic could be used as a substrate. If ceramic substrates continue to be used in the electronics industries, they will be limited to high-performance type of products, such as single crystals or diamond.

Development of Ceramic Capacitors

Natural materials such as mica have historically been used in capacitors for a long time. Electrolyte capacitors use an aluminum oxide thin film as a dielectric. Several other oxides have been used as capacitor materials for many years.

It is well-known that barium titanate has a high dielectric constant (several 1000 or more). This ceramic was independently developed and studied in USA, Japan, and the Soviet Union. The abnormalities of the dielectric constant of barium titanate were discovered by Wainer and Salomon in 1942, which was an important breakthrough in the application of ceramics after World War II. Subsequently, Vul and co-workers, von Hippel, and Ogawa and Waku studied the ferroelectric properties of barium titanate.

However, from the point of its practical use, it is important to note that it took a remarkably long time from the discovery of barium titanate as a substance to its development as a ceramic capacitor. It was actually in the 1990s that the ceramic capacitor with a multilayer-type structure using barium titanate came to be loaded into almost all electric devices. This is because it took time to develop the process of manufacturing multilayer ceramic capacitors on a large scale. A process using the doctor blade method is first used to form thick films, and it is necessary to carry out the lamination of films. The technical developments, other than that of a ceramic layer, were also important. The development of conductive layers using nickel for an internal electrode was also a key factor in the development of the technology.

History of Piezoelectric Ceramics

The piezoelectric effect was discovered by Jack and Pierre Curie in 1880. Materials that display the piezoelectric effect need to be in the form of single crystals. Therefore, in order to use this effect for practical purposes, single crystals of appropriate materials were produced industrially. In Japan, Toyo Communication Equipment industrialized the production of quartz by the hydrothermal method in 1959.

Other materials were also studied for use as piezoelectric ceramics. Since it was reported by Bell Laboratories in 1963 that the thin film of CdS worked as a piezoelectric transducer, development of piezoelectric thin films and thick films started. The development of the thick-film process and materials that were more suitable for mass production attracted much attention. PZT, that is, $\text{Pb}(\text{Zr}, \text{Ti})\text{O}_3$, discovered in the late 1950s, became the primary candidate for practical applications. A phase transition occurs when the Zr/Ti ratio is 53/47. In the vicinity of the phase boundary with this composition, the dielectric constant and the piezoelectric constant become the maximum.

In order to make a piezoelectric body of this composition, materials with random orientation cannot be used. Therefore, polarization processing was indispensable during sintering and the related process itself had to be developed. A number of sheets must be laminated as a layer, especially in the case of an actuator; thus, the manufacturing technology acquires key importance.

In Europe, a restriction in the use of lead in electronic products will be in effect from the year 2006. PZT, of course, contains lead. It does not necessarily mean that this material will be prohibited from use in Europe soon, but it is also possible, that if a new material for replacement is developed, PZT will then be forbidden. Therefore, development of piezoelectric materials which do not contain lead is now in severe competition.

Ion Conductivity Ceramics

It has been known for many years that glass and other ceramics show an alkali ion conduction. For example, a group of substances called beta alumina, containing Na as a component (in spite of being known as alumina), have been known as Na ionic conductors for many years. Their crystal structures were analyzed in the 1950s.

The Na-S battery, which uses beta alumina as an electrolyte, was proposed as a large-sized rechargeable battery for load leveling after the oil crisis of the 1970s. The Na-S battery attained the level of practical use at last by a joint development of NGK Insulators and the Tokyo Electric Power Co., (the delivery track record in 2002 was set at 5000 kW).

Although historically, ZrO_2 has been used due to its very high chemical durability at very high temperature, it was already known at the end of the nineteenth century that ZrO_2 , with the addition of CaO or Y_2O_3 , has oxygen ion conductivity. This material attracted attention after its use as an oxygen sensor for automobile exhaust gas purification was proposed. As an oxygen sensor,

ZrO₂ plays the role of a solid electrolyte similar to that in fuel cells. A solid electrolyte-type fuel cell, on the other hand, has not yet reached a stage where it can be used in practical applications.

Development of Ceramic Sensors

It must be noted that a ceramic material used as a chemical sensor brings about an improvement in the performance of various electrical appliances. The range of home electrical appliances which were originally apparatuses that could only detect temperature, now also include appliances (such as air conditioners, microwave ovens, or refrigerators) which can detect humidity, carbon dioxide, infrared radiation, etc. This development has been required from the viewpoint of increasing energy efficiency in relation to global warming and other environmental issues. In addition, detection of flammable gas, such as hydrogen, methane, and a liquefied petroleum gas, is indispensable because of concerns of safety. A gas sensor that made use of SnO₂ was developed. The principle of a gas sensor itself is rather conventional. The ZrO₂ sensor already mentioned is the so-called concentration cell type, and the principle is also classic.

The SnO₂-type gas sensor utilizes the characteristics of compounds as semiconductors, along with the capability of gas adsorption. It has, therefore, been an important target in its development as to how the most suitable textures and microstructures could be formed in ceramics to enhance the properties of adsorption of thick-film materials.

There are several ways for a modified usage of ion-conducting ceramics to detect a certain gas. One is to use ion-conducting ceramics together with the auxiliary electrode, which consists of the conduction ion and detection gas components. For example, in the case of the carbon dioxide sensor using beta alumina, NaCO₃ (containing Na⁺, the conduction ion of beta alumina) and the carbon dioxide of the detection gas will be used as the auxiliary electrode. Many approaches for development range between such theoretical understanding and the practical design of a sensor (see section "Further reading").

Ferrite Materials and Magnetic Recording

A ferrite, which is a magnetic oxide body, was invented by Takei and Kato in the 1930s. Ferrites are widely used as a core material for a transformer or magnetic heads. The oxide permanent magnet was also invented during almost the same period, and after that, it has been used as a low-cost permanent magnet material. Iron oxide ceramic powder is used as a magnetic recording material in videotapes such as VHS. A record system may change to a perpendicular type and oxide powder may be used again, although currently metallic materials are used for the purpose of high-density recording.

Ceramic Turbocharger and Ceramic Turbine

Silicon nitride and silicon carbide, which are the main components of nonoxide ceramics, are artificial compounds. Since these compounds have a strong covalent bond in nature, till 1960 it was accepted that they could not be sintered.

The first oil shock pushed the development of efficient energy devices, and the use of ceramic materials, which can be employed at much higher temperatures, was pursued. It was proposed in the 1980s that nonoxide ceramics could be used as parts of a gas turbine. The ceramic gas turbine project (CGT) was actually undertaken from 1988 to 1999 in Japan. A CGT with 300 kW power for co-generation and a 100 kW CGT for automobile use were developed. However, it has not reached the stage of commercial production, mainly because of production costs.

Ceramic turbocharger turbine blades made of silicon nitride are an example of a practical application of a nonoxide. Ironically, the material originally developed for raising energy efficiency was used in the automobile industry, which aimed at producing fuel-inefficient cars. However, the ripple effect was large. Nonoxide ceramics now have several applications, which are growing steadily.

Superconducting Ceramic Materials

In 1986, an oxide superconductor of the lanthanum–barium–copper system was first announced by Bednorz and Muller of the IBM Zurich Research Institute and its critical temperature T_c was 35 K, which exceeded the historical T_c 23 K of the NbGe. The Y–Ba–Cu system oxide was discovered in the following year and the critical temperature exceeded 77 K, which is the temperature of liquid nitrogen. Then, various new compound oxides, such as the Hg system, the Tl system, and the Bi system, were announced.

A F Hebard and others have reported that the powder of C₆₀ with doped potassium (K₃ C₆₀) shows a superconducting nature at a critical temperature of $T_c = 18$ K, and the same thin film of K₃ C₆₀ shows the superconducting nature at a critical temperature of $T_c = 16$ K. MgB₂ has recently been reported to become superconducting at 39 K (for further details, see section "Further reading"). Thus, superconductivity is serving as a frontier of the science of new compounds in the ceramics system.

Optical Fibers

In 1964, Nishizawa succeeded in developing graded-index-type optical fibers for communications.

In 1966, Kao found that if heavy metals contained in glass were removed, the absorption loss of light in glass decreased dramatically. This epoch-making discovery was the key to utilizing an optical fiber and one that enabled the material development

of low-loss fibers. Kao also had the foresight of proposing the structure of today's optical fibers consisting of a clad with a low refractive index and a core with a high refractive index glass.

Following the basic work of Nishizawa and Kao, Corning Inc. succeeded in making low-loss (20 dB km^{-1}) fibers. Subsequently, the basic technology of the present-day information technology grew through a stiff competition in the development of optical fibers.

Conclusion

Ceramics are practically useful materials. From their discovery, through application development and testing (the so-called seed-driven route), ceramics have come a long way. However, new materials with superior properties continue to be desired in a variety of application areas. Given the limitations of the global environment, exploring new ceramic materials is a real challenge for further sustainability.

This article deals with generalities and definitions of porous silicon (PSi): fabrication techniques, structural properties, chemical properties, electronic properties, electrical properties, optical properties, and actual or potential applications of PSi. Optical properties include light transport, photoluminescence (PL), and electroluminescence (EL).

Generalities and Definitions

PSi was discovered by Uhlir in 1956 while performing electrochemical etching of silicon. In 1990, Canham showed that certain PSi materials can have large PL efficiency at room temperature in the visible: a surprising result, since the PL efficiency of bulk silicon (Si) is very low, due to its indirect energy bandgap and short nonradiative lifetime. The reason for this was the partial dissolution of silicon, which causes (1) the formation of small silicon nanocrystals in the PSi material; (2) the reduction of the effective refractive index of PSi with respect to silicon, and hence an increased light extraction efficiency from PSi; and (3) the spatial confinement of the excited carriers in small silicon regions where nonradiative recombination centers are mostly absent. In general, PSi is an interconnected network of air holes (pores) in Si. PSi is classified according to the pore diameter, which can vary from a few nanometers to a few micrometers depending on the formation parameters (**Figure 1**). According to the general classification of porous materials, three size regimes are defined as in **Table 1**.

The word 'nanoporous' is sometimes used for the smallest-pore regime to emphasize the nanometric dimension. The volumetric fraction of air of the material is called porosity (P). The internal surface of PSi per unit volume can be very large, of the order of $500 \text{ m}^2 \text{ cm}^{-3}$. The enhanced PL efficiency of PSi—compared to Si—has motivated research toward other porous semiconductor materials. For example, highly porous SiC, GaP, $\text{Si}_{1-x}\text{Ge}_x$, and Ge structures have been investigated.

Fabrication Procedures

Anodization

PSi is mostly fabricated by electrochemical anodization—often referred to as electrochemical etching—of bulk Si wafers in diluted aqueous or ethanoic hydrofluoric acid (HF). Ethanol is often added to facilitate evacuation of H_2 bubbles, which develop during the process. Typical anodization arrangements are schematically shown in **Figure 2**. Another much less common technique is stain etching, or chemical etching (with no current flow), performed with HF– HNO_3 solution.

Table 1 IUPAC classification of porous materials

Dominant pore width (nm)	Type of material
≤2	Microporous
2–50	Mesoporous
>50	Macroporous

The anodization can be performed either in potentiostatic (voltage-controlled) or in galvanostatic (current-controlled) mode. The latter is normally preferred, because it supplies the required charge for the reaction at constant rate, regardless of any evolution – during anodization – of the cell electrical impedance, ultimately leading to more homogeneous and reproducible material. The typical values of the most important anodization parameters, along with their impact on the anodization process, are reported in **Tables 2 and 3**. Three sample setups for fabrication of different PSI structures are shown in **Table 4**. The anodization can be modulated. The modulation is most easily achieved by varying the applied current density. Modulation results in controlled changes of the microstructure and the porosity of PSI along the growth direction. For example, PSI multilayer films can be simply created by varying the current density in time.

The position of pore nucleation can be controlled by etch pits, defined by a lithographic step before the anodization (**Figure 3**). This option is in practice limited to macroporous PSI, since present lowest lithographic resolution limits are in the range of a hundred nanometers. For example, ordered two-dimensional periodical matrices of pores can be formed, leading to materials with remarkable optical transport properties (2D photonic crystals, see **Figure 4**). PSI singlelayers or multilayers can be fabricated as free-standing samples. The detachment from the substrate can be achieved by applying a short pulse of high current density, that is, exceeding the electropolishing threshold, typically some hundreds of mA cm^{-2} .

Anodization Mechanisms

Typical current–voltage (I – V) characteristics of the electrochemical cell are shown in **Figure 5**. It should be stressed that the quantity having physical meaning is the current density J (at the Si/electrolyte interface), rather than the absolute current I . J and I scale with a fixed constant for a given cell, provided that the area of the Si sample exposed to the electrolyte is well defined and fixed.

In order to form PSI, the current at the Si side of the Si/electrolyte interface must be carried by holes, injected from the bulk toward the interface. The current must be kept between zero and the electropolishing threshold, which can be identified as the value of the first maximum of the anodic regime in the I – V curve. Useful regimes are included in the hashed region of **Figure 5**, where the electropolishing threshold voltage (for the curve marked with open circles) is $V \sim 1.3$ V. In order to achieve significant hole current in n -type Si, external illumination of the sample is required, depending on the doping level. If the current exceeds the electropolishing threshold, the anodization results in a progressive, complete removal of Si. The wafer then has a mirror-like appearance.

A hypothesized chemical reaction which could describe the anodization is .

The last term – a negative charge at the interface, to be neutralized by the current flow – would explain the need of hole injection from the substrate toward the Si/electrolyte interface. Similar to most semiconductor junctions, at the Si/electrolyte interface a

Figure 2 Schematic anodization arrangements: (a) principle and (b) practical examples (A, B, and C). Platinum and Teflon are mostly used because of their chemical resistance to HF. In the practical arrangements A, B, and C, the Si area exposed to the solution—typically $\sim 1 \text{ cm}^2$, circular—is well defined by the Teflon cell. Rubber gaskets between Si and Teflon can easily avoid spills. Type A is easier to design, type B is convenient when Si illumination is desirable (e.g., for *n*-type Si, see section ‘Fabrication procedures’), and type C does not require electrical contacts on Si. An optional stirrer is sometimes used to improve diffusion of HF during the anodization and H bubbles removal.

Table 2 Critical parameters of the anodization procedure

Parameter	Typical range	Unit
HF concentration	2–40	% (in weight)
Current density	0.5–150	mA cm^{-2}
Anodization time	5–1800	s
Temperature	250–300	K
Wafer resistivity (<i>p</i> -type)	0.001–100	$\Omega \text{ cm}$
Wafer resistivity (<i>n</i> -type)	0.001–100	$\Omega \text{ cm}$

Source: A typical electrochemical solution can include, for example, water (H_2O) in an approximately equal amount of HF, the rest being ethanol.

depletion zone is formed. The width of this depletion zone depends on the doping and may explain the different pore sizes found in p^- - and p^+ -type doped silicon. In addition, the depletion layer width depends on the surface curvature: the anodization preferentially occurs at the pore tips where the curvature is largest. Moreover, when the depletion zones of adjacent pores meet each other, the current flow is suddenly pinched off. Further Si etching is blocked, and pore collapsing is prevented. For this reason, the reaction is self-limited in the hashed anodization regimes of Figure 5, and leads to a porous structure rather than to electropolishing. As further

Table 3 Effect of anodization parameters on PSi formation

An increase of	Porosity	Etching rate	Electropolishing threshold
HF concentration	Decrease	Decrease	Increase
Current density	Increase	Increase	
Anodization time	Increase	Almost constant	Increase
Temperature			Increase
Wafer doping (p -type)	Decrease	Increase	
Wafer doping (n -type)	Increase	Increase	

Source: As an approximate rule of thumb, the etch rate is of the order of 1 nm s^{-1} for each mA cm^{-2} of the anodization current density.

Table 4 Three sample sets of anodization parameters, for p -type Si substrates, resulting in the three different structural regimes described in Table 1

HF concentration (%)	15	15	2
Current density (mA cm^{-2})	50	50	5
Wafer resistivity ($\Omega \text{ cm}$)	5	0.01	10
Resulting structure	Microporous	Mesoporous	Macroporous

**Figure 3** Schematic lithographic procedure resulting in the definition of pore-starting etch pits.

practical consequence, in stationary conditions, the porosity remains approximately constant, whereas the overall thickness of the PSi layer grows essentially linearly in time.

Back-side illumination (most conveniently achieved using cells of type B, Figure 2) in potentiostatic regime, with n -type Si, allows a useful, further control on the hole injection, both in terms of carrier flux (which is proportional to illumination intensity) and of localization of the injection, which is concentrated in the region of the pore tips, acting as hole collectors. The etching process leads to a very regular pore growth, which is most effectively exploited to fabricate macroporous photonic crystal devices (Figure 4).

Drying Techniques

Due to large capillary stress, drying of samples is a critical step and can result in extended cracking if special procedures are not followed. Methods to reduce or eliminate the capillary stress include pentane drying, supercritical drying, freeze drying, and slow evaporation rates. Pentane drying is the easiest to implement. Pentane has a very low surface tension, and shows no chemical interaction with PSi (unlike ethanol). Using pentane as drying liquid enables to strongly reduce the capillary tension, but since water and pentane are nonmiscible liquids, ethanol or methanol have to be used as intermediate liquids. Using this drying technique, PSi layers with porosity values up to 90% and thickness up to $5 \mu\text{m}$ exhibit no cracking pattern after drying. Super-critical drying

Figure 4 Example of a photonic crystal (cross section and top-view images of the same sample) realized with ordered macroporous PSi in a *p*-type doped silicon substrate. This photonic crystal has a photonic bandgap at $3.5\ \mu\text{m}$.

Figure 5 Typical I - V characteristics of an electrochemical cell for PSi fabrication (Figure 2). The hashed region corresponds to the useful regime where PSi can be achieved, assuming the I - V characteristic marked with hollow circles. In the anodic regime, the characteristics of a cell with *n*-type Si will lie in the region bounded by the characteristic in dark (dashed line) and in full light (hollow circles).

requires a specific apparatus but is more effective in preventing cracking of the film so that PSi layers of porosity values up to 95% were demonstrated.

Oxidation Techniques

As soon as PSi samples are dried, hydrogen surface passivation is gradually replaced by native oxide. This chemical change affects most PSi properties, for example, PL and electrical conductivity. Since the characteristics of the native oxide strongly depend on many factors such as the storage conditions, evolution of sample properties is often poorly characterizable. To stabilize PSi properties, oxidation is often used. Oxidation implies the formation of a layer containing the original Si

atoms. Therefore, it also reduces the nanocrystallite size, with remarkable impact on PL emission energy (blue-shift). The employment of controlled oxidation procedures is therefore a valuable post-anodization option toward a better control of PSi properties and stabilization.

Tested oxidation procedures on PSi include anodic oxidation, chemical oxidation, thermal oxidation, plasma-assisted oxidation, and irradiation-enhanced oxidation. Anodic oxidation is an electrochemical process, in which oxide layers are formed with current injection. As such, the technique is structurally selective: more conductive paths get more oxidized. This selectivity is particularly interesting for light-emitting diode (LED) applications, where more conductive paths are usually associated to large injection channels, which are poorly luminescent, and their oxidation results in enhanced EL quantum efficiency. Another application of controlled oxidation – mostly thermal – is the fabrication of small, blue-luminescent PSi nanocrystallites.

Structural Properties

Structural properties of PSi have been investigated by electron microscopy, scanning probe microscopy, X-ray scattering techniques, X-ray absorption techniques, and Raman spectroscopy. In particular, X-ray absorption spectroscopy can be performed not only by extended X-ray absorption fine structure (EXAFS) analysis, but also by X-ray excitation of optical luminescence (XEOL), a convenient tool for luminescent samples, in which absorption is probed via the measurement of the corresponding optical emission. A general feature resulting from the comparison of these techniques is that highly luminescent PSi is a composition of extensively connected Si crystals of nanometric dimensions (typically, 1–5 nm in radius). Sizes smaller than Si Bohr radius (~ 4.9 nm), imply significant quantum confinement effects. Raman measurements are also often used to demonstrate crystallinity in PSi skeleton and infer information on the size of Si nanocrystals.

Accurate determination of pore size distribution in mesoporous Si is usually given by the analysis of adsorption isotherms of gases at low temperature (Brunauer–Emmett–Teller, or BET, method). The physical adsorption by a porous surface is increased relative to a nonporous one because of capillary condensation in pores. This increase in adsorption starts when the gas pressure is high enough to fill the smallest pores.

Chemical Properties

Surface chemical composition of PSi is best probed with Fourier transform infrared (FTIR) spectroscopy. FTIR signal in PSi is larger and easier to measure than in bulk Si due to much larger specific area. Chemical bonds and their IR resonance positions detected in PSi are shown in Table 5. In fresh, as-prepared samples, oxygen is normally absent, the dominant bonds being Si–H_x groups ($x = 1, 2, \text{ or } 3$). Aging is observed as a slow replacement of H by O bonds in PSi. Also, luminescence fatigue is explained by photochemical reactions occurring on the surface of the Si nanocrystals.

Electronic Properties

The first and most favorable explanation for the visible emission in PSi is the quantum confinement of excitons in nanometer-sized silicon. An empirical law, based on the effective mass approximation, links the energy gap E_g of silicon nanocrystals with their sizes ℓ : $E_g(\ell) = E_g^{\text{Si}} + 88.34/(\ell)^{1.37}$ (eV), when ℓ is given in Å. The energy gap opening is given by an equal energy shift of the bottom of the conduction band to high energy and of the top of the valence band to low energy. The nature of the energygap is still indirect even though a quasidirect bandgap can be formed in ultrasmall Si nanocrystals.

Electrical Properties

Electrical resistivity in PSi is five orders of magnitude higher than in intrinsic Si, because PSi is depleted of free carriers. Depletion can occur either because of the energy gap widening from quantum confinement which reduces the thermal generation of free carriers, or because of trapping of free carriers. Trapping can occur during the preparation of PSi either because the binding energy of dopant impurities are increased or because of the formation of surface states. It has been demonstrated that the dopants are still present in essentially unchanged concentration after the etching, but are in a neutral state.

The electrical transport is mainly affected by the disordered structure of the Si skeleton which restricts the conductive paths to a highly constrained geometry, which for certain porosities forms a percolated or fractal geometry. As a consequence, conductivity is thermally activated, strongly frequency dependent, and highly dispersive. Several models have been proposed to explain the electrical transport properties. They differ on the transport paths and mechanisms. The proposed transport paths range from transport in the Si nanocrystals (with diffusion or tunneling between the Si nanocrystals or at their surface) to transport in the amorphous and disordered matrix surrounding the nanocrystals, or through both. The suggested mechanisms are band transport, activated hopping in band tail, trap-controlled hopping through nanocrystals, activated deep states hopping, Pool-Frenkle processes, and activated hopping in fractal networks.

Given the large specific area per unit volume, the electrical transport is strongly influenced by external factors such as residual electrolyte and ambient atmosphere. The latter property is very interesting for sensor applications. Certain gases – for example, NO₂ – have the capability of modifying the free carrier population. Changes in the electrical conductivity in the presence of sub-ppm concentrations of such gases can be detected at room temperature operation. Other gaseous species (e.g., polar liquid vapors) also affect electrical transport via electric field interactions with charge carriers.

Optical Properties

Light Diffusion and Scattering

The dimension l of the PSi structures (i.e., the pore size and the porous layer thickness), compared to the optical wavelengths λ , can range from $l \ll \lambda$ all the way to $l \approx \lambda$. There are accordingly two different regimes of light propagation and interaction with PSi.

The first regime is $l \ll \lambda$. The radiation fields cannot resolve the PSi structures, and the interaction can be conveniently described by means of an ‘effective medium approximation,’ where a macroscopic dielectric constant (or a refractive index) is evaluated as a suitable combination of the dielectric constants of Si and air. The result is, in general, a complex dielectric function of space. Effective medium theories, which are routinely used for PSi, are enumerated in Table 6. Refractive index values are reported in Figure 6.

The second regime is $l \sim \lambda$. These kinds of structures are called mesoscopic: the structural size is small compared to the wave coherence length, that is, the maximum length along which phase memory and coherent phenomena are observable. The porous geometrical structure strongly influences light transport and interaction. Useful mathematical models take advantage either of the Bloch theorem (in the case of periodical structures (photonic crystals)), or of statistical and Green’s function methods (in the case of aperiodic or random structures).

Mixed regimes are also possible in PSi. The most important case is the one-dimensional (1D) mesoscopic structure: the anodization parameters are set to achieve microporous PSi (size of pores $\ll \lambda$, first regime), but the anodizing current density is modulated to obtain periodical or aperiodical thin layer structures (thickness $\sim \lambda$, second regime along the PSi growth direction). Each layer is different from adjacent layers in terms of porosity and thus of effective dielectric constant (and effective refractive index). Compared to other thin-film growth techniques, PSi has the advantage of allowing a continuous tuning of the refractive index over a wide range ($1.4 \ll n_{\text{eff}} \ll 1.4$), and of being a fast and cheap technique that can lead to structures of several hundreds of layers, with typical fabrication times ranging from few minutes to few hours.

In the presence of high-index liquids (and/or their vapors), the refractive index of the porous layer changes, affecting light transport properties. The effect can be exploited for gas sensors and biosensors applications.

PL

Microporous PSi structures have been reported to luminesce efficiently in the near infrared (IR) (0.8 eV), in the whole visible range, and in the near ultraviolet (UV) (Figure 7).

Table 6 Useful effective medium approximation for the dielectric function of PSi

Theory	Formula
Bruggeman	$P \frac{\epsilon_M - \epsilon_{\text{eff}}}{\epsilon_M + 2\epsilon_{\text{eff}}} + (1 - P) \frac{\epsilon - \epsilon_{\text{eff}}}{\epsilon + 2\epsilon_{\text{eff}}} = 0$
Maxwell Garnett	$\frac{\epsilon_{\text{eff}} - \epsilon_M}{\epsilon_{\text{eff}} + 2\epsilon_M} = (1 - P) \frac{\epsilon - \epsilon_M}{\epsilon + 2\epsilon_M} = 0$
Looyenga	$\epsilon_{\text{eff}}^{1/3} = (1 - P)\epsilon^{1/3} + P\epsilon_M^{1/3}$

Source: ϵ , dielectric function of Si; ϵ_M , dielectric function of host material (normally: air); ϵ_{eff} , calculated effective dielectric function; P , porosity.

Figure 7 Room temperature photoluminescence spectra for various PSI structures which have been oxidized or implanted with some selected impurities. Reproduced from Fauchet, P.M., Tsybeskov, L., Duttagupta, S.P., Hirschman, K.D., 1997. Stable photoluminescence and electroluminescence from porous silicon. Thin Solid Films 297(1–2), 254–260, with permission from Elsevier.

Such a broad range of emission energies arises from a number of clearly distinct luminescent bands, which are listed in Tables 7–9. In addition, PSI has been used as an active host for rare-earth impurities, for example, Nd or Er, or dye solutions. Direct energy transfer between PSI and the impurity or dye is demonstrated. The most efficient and studied emission is the slow (S) band because it can be excited by electrical injection. The most popular model for the PL – especially for the S-band – is excitonic radiative recombination subject to quantum confinement. Other models are surface states models, the siloxene model, defect models, the surface hydrides model, and the hydrogenated amorphous silicon model. Coexistence of more than one mechanism is likely.

S-Band

It can be tuned from close to the bulk silicon bandgap through the whole visible range. The large spectral width comes from inhomogeneous broadening and vibronic coupling of the radiative transitions. The S-band efficiency is not proportional to the

Table 7 PSI luminescence bands

Spectral range	Peak wavelength (nm)	Label
UV	~350	UV band
Blue-green	~470	Fast (F) band
Blue-red	400–800	Slow (S) band
Near IR	1100–1500	IR band

Table 8 Some spectral characteristics of the S-band

Property	Typical values	Comments
Peak wavelength	1100–400 nm	At 300 K, depends on porosity
PL external quantum efficiency	$\geq 5\%$	At 300 K, depends on porosity
FWHM	0.3 eV	At 300 K (8 meV in PSi microcavities)
PL decay times	$\approx 10 \mu\text{s}$	Strongly dependent on wavelengths, temperature and aging condition
Polarizability ratio	$P \leq 0.2$	
Fine structure under resonant excitation	Phonon replica at 56 and 19 meV	Heavily aged PSi, energies consistent with Si phonons

Table 9 Some spectral characteristics of the F-band

Property	Typical values	Comments
Peak wavelength	480 nm	UV excitation at 300 K
PL efficiency	$\geq 0.1\%$	External quantum efficiency UV excitation at 300 K
FWHM	0.4 eV	UV excitation at 300 K
PL decay times	1 ns	Independent on wavelength and excitation conditions

inner surface area: a ‘threshold’ porosity has to be exceeded to achieve an efficient luminescence. Postanodization chemical etching in HF, corresponding to a porosity increase, results in a strong rise in PL efficiency and a blue shift of the visible band. External quantum efficiencies higher than 0.1% are obtainable from high-porosity PSi layers of all types, but efficiency normally decreases in the order n^- -type, p^- -type, n^+ -type, and p^+ -type doped PSi. High porosity is essential for high visible PL efficiency. The inefficient luminescence observed from inhomogeneous material of low porosity originates from microscopic areas of high porosity. Isolated nanocrystals, produced by dispersing a colloidal suspension of PSi fragments on a glass coverslip, show external quantum efficiencies $\approx 88\%$, with a number of bright-to-dark nanocrystals in the suspension of only 2.8%. Thus, the average quantum efficiency of a PSi layer of 1% results from a statistical distribution of high and low quantum efficiency nanocrystals.

Phonon-assisted luminescence (vibronic-coupled transitions) is demonstrated by fine structure in resonantly excited PL at low temperature. Thus, the electronic and the vibronic structure of the luminescence of PSi are similar to crystalline Si, with an energy shift consistent with quantum confinement. At large confinement energies (>0.7 eV), no-phonon quasidirect transitions dominate, because of the breakdown of k -conservation under strong confinement.

The luminescence is polarized parallel to the exciting light. This is measured by recording the polarization ratio $\rho = (I_{\parallel} - I_{\perp}) / (I_{\parallel} + I_{\perp})$. ρ is zero on the IR band and nonzero on the S-band (tending to zero as the energy approaches that of the Si bandgap). The interpretation is that PSi is an ensemble of randomly oriented aspherical nanocrystals, preferentially aligned along the $\langle 100 \rangle$ direction. Recombining carriers have bulk-like wave functions which are sensitive to the shape of the nanocrystals.

Aging effects include a blue shift in the S-band and changes in the PL efficiency (both increasing and decreasing have been observed), which can be explained in terms of surface oxidation. Anticorrelation exists between the dangling bond density and the luminescence efficiency; thus, the effect of the oxidation depends on its passivation properties.

Other Bands

The F-band is observed only in oxidized PSi, and it is probably originated from contaminated or defective Si oxide. Annealing in water vapor activated the blue emission indicating a possible major role of adsorbed hydroxyls in the emission process. The IR band is weak at room temperature, and becomes much stronger at cryogenic temperatures. Its origin seems to be related to dangling bonds, although no direct correlation has been demonstrated.

Absorption

The absorption coefficient has been measured in PSi by optical transmission, photoluminescence excitation (PLE), and photo-thermal deflection spectroscopy (PDL). Transmission spectra are shifted toward higher energy compared to bulk Si with a shift, which increases with increasing porosity. This observation is consistent with quantum confinement model. The line shape analysis of the absorption coefficient shows that its energy dependence follows a trend like that of an indirect gap semiconductor similar to Si, but displaced to higher energy.

A characteristic feature of PSi is the large displacement (Stokes shift) between the absorption edge and the emission peak energy (see Figure 8). The existence of localized states that can account for the observed shift has been demonstrated. Such states can lead to self-trapped excitons at some surface bonds of Si crystallites, such as Si–Si dimers and Si–O double bonds, giving reduced

Figure 8 Compilation of optical bandgaps of PSi samples obtained from optical absorption (unfilled symbols) and luminescence (filled symbols). The lines represent calculated values with the empirical law reported in the text.

dependence of the luminescence energy on size, and a very large Stokes shift. Other models for the Stokes shift are based on Si quantum dot relaxation from distorted configurations, giving rise to new transitions involving localized states that lower the emission threshold with respect to the absorption.

Applications

Important actual or perspective applications of PSi are shown in [Table 10](#).

LEDs

Si *p/n* junction emits light both in forward and in reverse bias conditions. Power efficiency is $\sim 10^{-4}$ (10^{-8}) at 1.1 μm wavelength in forward (reverse) bias. Also in PSi based devices, EL is observed both in the IR and in the visible. Efficiency is higher than in bulk Si diodes, depending on the diode structure and on the PSi contact method. Initially, EL was observed with wet contacts and later with solid contacts. Major achievements in terms of quantum efficiency are summarized in [Figure 9](#).

Table 10 Potential application areas of PSi

Application area	Role of PS	Key property
Optoelectronics	LED	Efficient electroluminescence
	Waveguide	Tunability of refractive index
	Field emitter	Hot carrier emission
	Optical memory	Nonlinear properties

Sensors, Biosensors, Medical Applications

PSi is a twofold promising material for sensor applications. On one side, its electrical and optical properties strongly depend on the environment, because of its large specific area. Useful sensing parameters include, for example, the electrical conductivity and photoluminescence. Most sensing parameters can effectively work at room temperature. On the other side, it supplies a handy template to hold chemical and biological species. Target species can be immobilized in the PSi matrix, a practice which is especially useful for biological samples—such as oligonucleotides, biotin, or antibodies. Techniques for immobilization range from physical adsorption to the replacement of hydride bonds with Si alkyls, and to antibody bonding at functionalized PSi surface with subsequent antibody–antigen interactions. Species identification can be performed by probing optical, electrical, or chemical properties. Examples include, respectively, reflectivity or wave-guiding measurements (which depend on the dielectric constant of the species, as already discussed), conductance measurements, and pH measurements. Biocompatibility of PSi has suggested medical applications, such as *in vivo* slow release of drugs, *in vivo* diagnostic tests, and template for bone growth.

Abstract

Semiconductor alloys enable the band gap engineering in heterostructures widely used in optoelectronic devices. This article discusses the electronic properties of tetrahedrally coordinated crystals (group IV, III-V and II-VI semiconductors), and then uses these semiconductors as a model system to discuss chemical trends in semiconductor alloys and band gap engineering. Both the regular alloys and the highly mismatched alloys are described and compared for the three material groups. Additionally, the discussion of chemical trends in semiconductor compounds and alloys is extended to van der Waals crystals and perovskites, which are the next generation of semiconductors for optoelectronic devices.

Key points

- crystal lattice constant vs valence radius in the same group of semiconductors.
- band gap vs crystal lattice constant in regular semiconductor alloys.
- band gap vs crystal lattice constant in highly mismatched alloys.
- strain engineering in regular and highly mismatched alloys.
- chemical trends in the electronic band structure in van der Waals crystals and perovskites.

Introduction

As a result of arranging atoms in a periodic crystal lattice, we obtain a crystal that is characterized by a given symmetry and has specific mechanical, electrical and optical properties. These properties depend on the atoms and the symmetry of the crystal, i.e., the arrangement of the atoms. The same atoms arranged differently lead to crystals with different properties, and this is called polymorphism. The presence of stable crystalline compounds depends on the atoms and their arrangement as well as external conditions such as hydrostatic pressure or temperature. Among the semiconductors, the simplest and most studied system are those made of tetravalent elements, i.e., Si and Ge, which crystallize in the diamond structure. Another group that is equally well

[☆]Change History: April 2023. R. Kudrawiec rewritten the chapter and replaced figures.

researched, understood and widely used in the semiconductor industry is III-V compounds (GaAs, InP, GaSb, GaN, ...). Like Si and Ge, most of them exist in a cubic structure (mainly Zinc-Blende (ZB) structure) and share eight valence electrons per anion/cation pair. However, some of them (III-Nitrides: InN, GaN, AlN) prefer hexagonal structure but retain tetragonal coordination of atoms. Tetragonal coordination is also realized in the II-VI compounds, but many of them prefer an octahedral coordinated rock salt structure. This article discusses the electronic properties of tetrahedrally coordinated semiconductor crystals, and then uses these compounds as a model system to discuss chemical trends in the alloying of semiconductor compounds. A lot of attention has been devoted to semiconductor alloys, which enable the band gap engineering in semiconductor heterostructures widely used in various optoelectronic devices. In this case, both the regular alloys and the highly mismatched alloys are described and compared for the three material groups (IV, III-V and II-VI semiconductors). Additionally, the discussion of chemical trends in semiconductor alloys is extended to van der Waals crystals and perovskites, which are the next generation of semiconductors recently intensively explored.

Overview

Chemical bonding in tetrahedrally coordinated crystals

In tetrahedrally coordinated crystals such as C, Si or Ge the electronic states can be described approximately as superpositions of Pauling's sp^3 hybrid atomic orbitals, see Fig. 1. The same description can be applied to diatomic compounds such as GaAs or InP, but in this case we are dealing with two types of hybrids, those pointing toward and away from the nearest neighbors. They correspond to bonding and antibonding band states, i.e., the valence and conduction band, respectively. When two atoms in a unit cell differ slightly in electronegativity (case of GaAs or InP) then the bonds are covalent, as in Si or Ge. However, as the difference in electronegativity and valence radius increases, the nature of these bonds becomes more and more ionic.

Electronegativity and ionicity

In general, electronegativity is the tendency for an atom to attract electron density when forming a chemical bond in a given chemical element. The higher the electronegativity, the more an atom attracts electrons. The first precise electronegativity scale was proposed by Linus Pauling and was based on the energy of bonds as an extension of the theory of valence bonds (Pauling, 1932). This scale starts at 0.79 and ends at 3.98 and is known as the electronegativity in Pauling units (dimensionless quantity). Both the atomic number of an element and the distance at which its valence electrons are on the charged nucleus affect the electronegativity of the atom.

Fig. 1 Schematic illustration of the process of hybridization of s and p orbitals for carbon in the cubic diamond structure (left panel) and graphite (graphene) structure (right panel).

The ionicity of chemical bonds (polarity) characterizes a bond on a continuous scale from covalent to ionic bond, and electronegativity serves as a simple way to estimate bond ionicity. Usually, bonding is considered ionic where the ionic character is greater than the covalent character, but of course, a strict division into the nature of the bonds can be difficult in many cases and may not really be needed. Unlike covalent bonding, purely ionic bonding cannot exist because the close proximity of the atoms involved in the bond always allows some degree of sharing of the electron density between them. Therefore, all ionic bonding has some covalent character. Very often bonds with partially ionic and partially covalent character are called polar covalent bonds.

Very often electronegativity is a very good reference point for tracking changes in the band structure for semiconductor alloys as will be shown later in this chapter.

Electronic band structure

The electronic band structure (or simply band structure) of a given crystal is unique, as is the electronic structure of an atom. The band structure is obtained in the framework of the band theory, which is only an approximation to the quantum state of a solid, and applies to solids consisting of many identical atoms bonded together. Two factors determine the band structure of a perfect infinite crystal, i.e., the atoms and their arrangement. External factors such as pressure or temperature also influence the band structure, but this is a secondary effect.

In general, the band structure of a crystal describes the range of energy levels that electrons may have within it and the ranges of energy that they may not have (called band gaps). Imperfections in the crystal (point defect, impurities, dislocations) and the surface introduce additional energy states for electrons that are not discussed in this chapter.

To describe electronic states in solid state, the reciprocal lattice is introduced. This lattice exists in the space of spatial frequencies known as reciprocal space and represents the Fourier transform of a periodic spatial function in real space known as the direct lattice in which the arrangement of the atoms can be described (cubic, hexagonal lattice, etc.). While the direct lattice is the lattice of a crystal, the reciprocal lattice exists in the space of spatial frequencies known as k -space, where k refers to the wavevector of plane waves of the Fourier transform. In solid state physics, k -space is closely related to momentum space according to the proportionality $p = \hbar k / 2\pi$, where p is the momentum vector and $\hbar$ is the Planck constant. In this way k -space provides a way to visualize the results of the Fourier transform of a spatial distribution of atoms in crystal lattice and enables the assigning of energy states to the electron. The first Brillouin zone (k -space defined by the crystal symmetry) is used to represent the electron band structure for semiconductor compounds and alloys.

Thus, to describe the electronic states in a semiconductor crystal, we need to know the Brillouin zone for a given crystal structure (the Brillouin zone for the diamond structure and the zinc blend structure is shown in Fig. 2) and the dependence of the electron's energy on its wavevector in this space, i.e., k -vector. These relationships can be obtained under various models, including the kp model or the density-functional theory (DFT), which is a computational quantum mechanical modeling method used in solid state physics to investigate the electronic structure of many-body systems in condensed phases. Today, DFT is one of the most powerful and versatile methods available in condensed matter physics for studying electronic band structure. This method also makes it possible to test the stability of a given compound in a given crystal structure, which makes it very useful in band gap engineering.

The electronic band structure obtained within DFT method for Si is shown in Fig. 2. The most important information that can be extracted from the electron band structure presented in this form is the value of the energy gap, i.e., the energy distance between the top of the valence band and the minimum in the conduction band. In such a band model, the energy gap separates the energy states occupied by electrons (valence band) from the unoccupied states (conduction band) and determines the electrical and optical properties of a given crystal. An electron must appear in the conduction band or a hole in the valence band (i.e., a quasiparticle that describes the lack of an electron in the valence band) for such material to conduct electricity. It depends on doping, but for undoped semiconductors it depends on the width of the energy gap. Therefore, narrow-gap semiconductors show conductivity even in the absence of doping, while wide-gap semiconductors without doping and without defects and impurities are insulators. This means that a simple analysis of the band gap width gives an indication of the conductivity potential of a given crystal. In the case of optoelectronic devices such as light emitting diodes or laser diodes, the character of the energy gap (direct vs indirect) is a key issue. For Si the minimum of conduction band is close to the X point of Brillouin zone while the maximum of the valence band is in the center of Brillouin zone at the Γ point, see Fig. 2. In such a situation, for an electron from the conduction band to recombine radiatively with a hole from the valence band, phonons (lattice vibrations) are needed to fulfill the principle of conservation of momentum and energy. This is at least a three-particle process, which is much less likely than a two-particle process, i.e., the electron-hole recombination. Therefore, direct gap semiconductors, in which the conduction band minimum and the valence band maximum are at the same point in the Brillouin zone, are used for light emitters. In addition to the width of the band gap and its nature (indirect vs direct), many other parameters that are important for the engineering of bands in semiconductor devices, e.g., effective masses for electrons and holes, can be derived from the band structure. In this chapter only the band gap is analyzed because it is the most important parameter of the band structure that determines the electrical and optical properties of semiconductor compounds and alloys.

Group IV and chemical trends

Fig. 3 shows the band gap as a function of the crystal lattice constant for group IV (elemental) semiconductors: diamond, silicon, germanium, gray tin (α -Sn) in the diamond structure. As the atomic number for these atoms increases, the valence radius increases

Fig. 2 The Brillouin zone for the diamond structure and the zinc blend structure (upper panel). The electronic band structure of Si along the Γ -L and Γ -X path together with the marked direct and indirect energy gap (bottom panel).

(C—0.70 Å; Si—1.10 Å; Ge—1.25 Å; Sn—1.45 Å) and leads to a larger lattice constant of the crystal, see Fig. 3 (a). This is the expected trend, but when it comes to lead, the preferred structure is no longer that of a diamond. Lead exists in a face-centered cubic (FCC) structure and forms metallic bonds in which only the p -electrons are delocalized and shared between the Pb^{2+} ions. Note that the lightest element in this group, carbon, forms other stable allotropes including graphite, but with the tetrahedrally coordinated and covalently bonded cubic structure of the diamond, it is the most stable crystal. The series of these four elemental semiconductors (C, Si, Ge and Sn) makes it possible to follow the chemical trends in the band structure of tetrahedrally coordinated semiconductor crystals.

Going from light element to heavy, the band structure changes from wide-gap semiconductor (C) through typical semiconductor (Si), narrow-gap semiconductor (Ge) and reaching semimetal (Sn), see Fig. 3 (b) and (c). The valence orbitals that participate in the formation of the valence and conduction bands in these semiconductors have the same symmetry (s and p) but they originate from other period and this is the reason for the observed very significant changes in the electronic band structure. These changes can be correlated with the crystal lattice constant as a narrowing of the band gap with an increase in the crystal lattice constant, which appears to be a very general chemical trend in semiconductors when the crystallographic structure is preserved. This trend is intuitively understandable also from the point of view of simple models in quantum mechanics. By bringing the same atoms together in place of degenerate energy levels (the case of separated atoms), bonding (valence band) and anti-bonding (conduction band) states are created, separated from each other by an energy gap, which will be larger if the distance between the atoms (crystal lattice constant) is smaller. However, it should be remembered that as the atomic number increases, subsequent shells are filled and electrons from these shells affect the dispersion of the valence and conduction bands including the band gap. This, among other factors, makes α -Sn a semi-metal and Pb loses tetrahedral coordination and is present in the FCC structure. In addition, many other parameters (elastic constants or band gap) describing elemental semiconductors (C, Si, Ge, Sn) show similar chemical trends, i.e., a regular change with the increase of the crystal lattice constant.

Fig. 3 (a) Relationship between the crystal lattice constant and the valence radius for elemental IV semiconductors in diamond structure (blue diamonds) and lead in FCC structure (green square). (b) Electronic band structure for diamond, silicon, germanium and gray tin. (c) Relationship between the energy gap and the crystal lattice constant for group IV materials (diamond, silicon, germanium, and gray tin) in the diamond cubic structure.

III-V semiconductors and chemical trends

In III-V semiconductors, the cation (group III atom) is surrounded by four anions (group V atom) and vice versa. The valence electrons from the cation (two s electrons and one p electron) and the valence electrons from the anions (two s electrons and three p electrons) form bonding and anti-bonding sp^3 hybrid atomic orbitals. Unlike Si, they are not the same due to the different electronegativities of the two atoms. Therefore, the nature of the bonds changes from covalent to ionic. In this case, the bond ionicity can also be a measure for studying changes in the electronic band structure. However, the lattice constant is of great technological importance and is therefore used in these considerations.

When the atomic number for group III (or group V) atoms increases, the valence radius of the atom increases and the lattice constant of the ZB III-V semiconductor increases as well. In analogy to group IV semiconductors, one can expect chemical trends for group III-V semiconductors, and this is exactly the case, but the number of semiconductor compounds is much greater here, and chemical trends must be analyzed in appropriate subgroups.

Fig. 4 shows the band gap as a function of the lattice constant for III-V semiconductors in the ZB structure. To observe chemical trends, these compounds have been grouped as wurtzite III-nitrides (black hexagons), Al-V (blue squares), Ga-V (green squares), and In-V (red squares) compounds. The energy gap for many B-V compounds has not yet been investigated experimentally and therefore they are not shown in this figure. Nitrides are also present in ZB structure and therefore they are plotted in this figure together with Al-V, Ga-V, and In-V compounds. For all these groups it is clearly visible that the band gap narrows with the increase in the crystal lattice constant (going from N through P and As to Sb). Bismides, which are not plotted in this figure, are narrow gap semiconductors (AlBi) and semimetals (GaBi and InBi) that additionally confirm this trend.

Fig. 4 (a) Relationship between the crystal lattice constant and the valence radius for III-V semiconductors in zinc-blende structure. (b) Relationship between the energy gap and the crystal lattice constant for III-V semiconductors: solid points—direct band gap, open points—indirect band gap.

The same trend is observed looking for these compounds grouped with the fixed group V atom, i.e., nitrides, phosphides, arsenides, and antimonides going from Ga to In, i.e., the band gap narrows with the increase in the crystal lattice constant. Al-V compounds (AlN, AlP, AlAs and AlSb) are a little bit out of this trend due to a little bit smaller lattice constant going from Al to Ga. B-V compounds are not plotted in this figure as some of them (BP and BSb) are not well studied experimentally. However, it is worth emphasizing here that both Al-V and B-V compounds are indirect gap semiconductors.

Summarizing this analysis, clear and systematic changes are observed going from light elements to heavy elements: the material varies from a wide gap semiconductor through a semiconductor and a narrow gap semiconductor to a semi-metallic one.

II-VI semiconductors and chemical trends

In this group of semiconductors the tetragonal coordination of atoms is also realized, but many compounds from this group (MgO, MgS, MgSe, CdO) prefer an octahedral coordinated rock salt structure. In the ZB structure the cation (group II atom) is surrounded by four anions (group VI atom) and vice versa. Like Si and Ge, the valence electrons in ZB structure of II-VI semiconductors form bonding and anti-bonding sp^3 hybrid atomic orbitals sharing eight valence electrons per anion/cation pair, but only two electrons are from the cation (two s electrons) and as many as six electrons are from the anion (two s electrons and four p electrons). Therefore, some of tetrahedrally coordinated crystals prefer wurtzite (W) structure (BeO, ZnO, HgO) and many others like MgO, MgS, MgSe, CdO, HgS, prefer an octahedral coordinated rock salt (RS) structure.

The relation between the band gap and the lattice constant for II-VI semiconductors is shown in Fig. 5 with a clear distinction of the crystallographic structure (squares—ZB; hexagons—W; diamonds—RS). As seen most of the semiconductors in this family of

Fig. 5 Relationship between the energy gap and the crystal lattice constant for II-VI semiconductors: solid points—direct band gap, open points—indirect band gap.

compounds are ZB crystals, which exhibit chemical trends similar to those observed in group IV and III-V semiconductors, i.e., the band gap narrows with the increase in the crystal lattice constant (going from S through Se to Te). The same trend is observed looking for these compounds grouped with the fixed group VI atom, i.e., for sulfides, selenides, and tellurides.

It is also worth noting that changes in the preferred crystallographic structure are also correlated with chemical trends. Going to compounds with oxygen, i.e., the lightest atom in group VI, which has the smallest radius and the greatest electronegativity, the compounds occur in the wurtzite or rock salt structure. In the case of group II atoms, the heaviest atom is Hg, which, when bonding to S, prefers a structure other than ZB (i.e., RC—red cinnabar), while for bonding to the heaviest group VI atoms (Se or Te, which are similar in terms of electronegativity and valence radii), the preferred crystal structure for HgSe and HgTe is the ZB structure. Cadmium is very similar in this respect: CdTe, CdSe and CdS prefer the ZB structure, but CdO occurs in the RS structure. The Mg-VI compounds are less explored experimentally than the Cd-VI compounds, but they seem to prefer the RS structure especially the MgO compound.

Alloys

An alloy semiconductor is a combination of two or more semiconductors, i.e., elemental semiconductors (Si with Ge) or semiconductor compound from the same group (GaAs with InAs or ZnS with ZnSe). An alloy crystal is often called a mixed crystal or a solid solution. Note that the alloy is formed from a physical mixture of two or more compounds, while a compound is formed from a chemical reaction. For example, GaAs (or InAs) is not an alloy, it is a compound consisting of Ga (In) atoms bonded to As atoms. $\text{Ga}_{1-x}\text{In}_x\text{As}$ is an alloy compound consisting of GaAs and InAs with a mole ratio of $(1-x):x$. The bonds in GaAs and InAs have characteristics intermediate character between the covalent and ionic terms.

Like $\text{Ga}_{1-x}\text{In}_x\text{As}$, $\text{Si}_{1-x}\text{Ge}_x$ is an alloy semiconductor composed of elemental semiconductors where the bonds Si-Ge, Si-Si and Ge-Ge can still be described by the covalent term. However, silicon carbide (SiC with a mole ratio of 0.5:0.5) is a compound, not an alloy, even though it is composed of elemental semiconductors (Si and C). This is that the chemical bonds in SiC cannot be described only by the covalent term present in the diamond structure. They have characteristics intermediate to those associated with the covalent and ionic terms, because of the large difference in electronegativity of the atoms (1.90 (Si) vs 2.55 (C) in contrast to 2.01 (Ge) in $\text{Si}_{1-x}\text{Ge}_x$). Therefore, SiC is the case of a compound with only Si-C bonds, where Si-Si and C-C bonds are treated as imperfections in the periodic lattice.

An alloy with two components is called a binary alloy; one with three is a ternary alloy; one with four is a quaternary alloy; one with five is a quinary (or a pentanary) alloy. The resulting alloy has properties, including the band structure, different from those of its components, i.e., elemental semiconductors or semiconductor compounds. Electronic band parameters of semiconductor alloys and their dependence on the composition of the alloy are very important in the engineering of semiconductor heterostructures. Therefore, a lot of attention has been paid to these problems in the past, and they are still being intensively explored for new alloys. So far, it has been observed that parameters such as crystal lattice constant, elastic constants or other parameters related to mechanical properties can be described by linear interpolation, while parameters related to the band structure (band gap, splitting of spin-orbit band, etc.) show deviations from such interpolation. The greater the difference in electronegativity of isovalent elements in the alloy, the greater the deviations from linearity. Alloys consisting of similar elements can usually be obtained with a full range of compositions and are called regular semiconductor alloys. $\text{Si}_{1-x}\text{Ge}_x$ and $\text{Ga}_{1-x}\text{In}_x\text{As}$ are good examples of regular alloys.

The crystal lattice constant for $\text{Ga}_{1-x}\text{In}_x\text{As}$ (a^{GaInAs}) can be calculated from linear interpolation:

$$a^{\text{GaInAs}} = (1-x)a^{\text{GaAs}} + xa^{\text{InAs}} \quad (1)$$

where a^{GaAs} and a^{InAs} is the crystal lattice constant for GaAs and InAs, respectively, and x is the mole fraction of InAs in $\text{Ga}_{1-x}\text{In}_x\text{As}$ alloy.

The band gap for $\text{Ga}_{1-x}\text{In}_x\text{As}$ (E_g^{GaInAs}) at the Γ point of Brillouin zone can be calculated by interpolation:

$$E_g^{\text{GaInAs}} = (1-x)E_g^{\text{GaAs}} + xE_g^{\text{InAs}} - bx(1-x) \quad (2)$$

with the bowing parameter (b) describing the deviation from linearity. For this alloy the bowing parameter equals 0.47 eV. E_g^{GaAs} and E_g^{InAs} is the band gap at the Γ point of Brillouin zone for GaAs and InAs, respectively.

Fig. 6 shows the dependence of the direct energy gap in this alloy on the composition (panel a), the dependence of the crystal lattice constant of the $\text{Ga}_{1-x}\text{In}_x\text{As}$ alloy on the composition (panel b) as well as the change of the energy gap as a function of the crystal lattice constant (panel c), which results from these two dependencies shown on the panel (a) and (b). Analogous relationships can be plotted for those alloys of groups IV, III-V, and II-VI, in which the semiconductors are present in the same crystal structure. However, within the same crystal structure, semiconductors can differ significantly in terms of the valence radii of the anions (cations) and their electronegativity. Alloys of such semiconductors were distinguished by Walukiewicz and named Highly Mismatched Alloys (HMAs) (Walukiewicz and Zide, 2020). Examples of HMAs are $\text{C}_{1-x}\text{Ge}_x$, $\text{GaN}_{1-x}\text{As}_x$, and $\text{ZnO}_{1-x}\text{Se}_x$ for group IV, III-V, and II-VI semiconductors, respectively, and they are discussed in a separated section.

Fig. 6 Dependence of the direct energy gap (a) and the crystal lattice constant (b) of the $\text{Ga}_{1-x}\text{In}_x\text{As}$ alloy on the molar fraction of InAs. Changes in the direct energy gap of the $\text{Ga}_{1-x}\text{In}_x\text{As}$ alloy as a function of its crystal lattice constant (c).

Polymorphism and ordering

Polymorphism means the existence of a solid material in more than one crystal structure. In general, many compounds exhibit polymorphism. In this case, a good example to illustrate this phenomenon is SiC, which was previously discussed. In this material Si is tetrahedrally coordinated by C and vice versa. Various types of SiC differ one from another only by the order in which successive planes of Si (or C) atoms are stacked along the c axis, see Fig. 7. One polytype is the zinc-blende structure (3C) while the remainder, including two of the more frequently occurring forms, 4H and 6H (hexagonal), and 15R (rhombohedral), possess uniaxial symmetry (Wu et al., 2015). Each of these polytypes has a different band gap, and different Brillouin zones must be used to describe the electronic band structure for these crystals, and these zones result from the lattice system in which the crystal is described. In this case, SiC is a good example where the same atoms arranged differently lead to crystals with different electronic structure and different optical, electronic and mechanical properties.

Note that SiC is a compound but can be considered as an ordered alloy in which each Si atom is surrounded by four C atoms. In general, the same situation can be present in $\text{Si}_{1-x}\text{Ge}_x$ at $x = 0.5$, but the differences in the electronegativity of Si and Ge atoms are smaller, the bonds are more covalent than SiC, and therefore not every Si atom is surrounded by four Ge atoms, and not every Ge atom is surrounded by four Si atoms (Jager, 1995). This phase exhibits long-range order rather than random arrangement typical for alloys. An ordered alloy phase has been found not only in $\text{Si}_{1-x}\text{Ge}_x$, but also in many III–V and II–VI semiconductor alloys (Mascarenhas, 2002). In general, polymorphism and ordering are features of crystals that are not desirable in materials used in semiconductor devices because they make it difficult to control the homogeneity of the material properties. Therefore, random alloys are the ones that are desirable in band engineering in semiconductor heterostructures.

Key issues

Highly mismatched alloys

Semiconductor alloys consisting of anions (cations) that differ significantly in electronegativity or the valence radius of atoms are usually difficult to achieve and therefore very often they are not studied in the full range of compositions. HMAs contain elements with very different properties. These alloys are not well described by virtual crystal approximations or bowing parameter modified model. The parameters describing the band structure (e.g., energy gap) show very large deviations from the interpolation with a small square term (small bowing parameter) introduced to Eq. (2) as a correction to linear interpolation. Therefore, HMAs can be

Typical examples of HMA's in group III-V are nitrogen-diluted III-V semiconductors (dilute nitrides) and III-N diluted with group V atoms. They are the same alloys but are divided into two subgroups because they do not mix in the full range of compositions in the crystalline form, and the extreme compositions occur in different crystallographic structures, i.e., III-N prefer the wurtzite structure. In general, the alloying of GaN with GaAs was achieved in the whole range of compositions by lowering the growth temperature in the epitaxial process, but it was an amorphous material when the growth temperature was too low and the composition was far from binary compounds (Yu et al., 2009).

II-VI alloys have been less extensively studied than III-V alloys mainly due to the toxicity of Cd and Hg, which limits their application. Due to the high ionicity of the bonds in II-VI alloys many of them are considered unstable in semiconductor devices and this is another reason why III-V alloys dominate in optoelectronic devices. However, it should be remembered that mid-infrared detectors are still manufactured based on $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ alloy. Most of II-VI alloys obtained so far ($\text{Zn}_{1-x}\text{Cd}_x\text{S}$, $\text{Zn}_{1-x}\text{Cd}_x\text{Se}$,

$\text{Zn}_{1-x}\text{Cd}_x\text{Te}$, $\text{ZnS}_{1-x}\text{Se}_x$, $\text{ZnSe}_{1-x}\text{Te}_x$, $\text{Cd}_{1-x}\text{Hg}_x\text{Se}$, $\text{Cd}_{1-x}\text{Hg}_x\text{Te}$, ...) can be treated as regular alloys, but II-VI compounds (ZnS , ZnSe , ZnTe) diluted with oxygen (dilute oxides) and ZnO diluted with S (or Se) should be treated as HMAs (Welna et al., 2014; Welna et al., 2015). The group of II-VI alloys also includes those that have not been synthesized so far and that can be treated as HMAs by looking at the differences in electronegativity of atoms and their valence radii ($\text{Be}_{1-x}\text{Hg}_x\text{S}$ or $\text{Be}_{1-x}\text{Hg}_x\text{Se}$).

Band anticrossing model

For HMAs, the electronic band structure cannot be described in terms of the virtual crystal approximation, and the changes in the band gap as a function of composition are difficult to approximate by Eq. (2), because the bowing parameter reaches large values and the dependence deviates from the parabolic one. Therefore, the band anticrossing (BAC) model (Shan et al., 1999; Wu et al., 2002), is often used to describe the electronic band structure of HMAs including the band gap. Originally, this model was proposed by Walukiewicz and coworkers to explain the pressure dependence of optical transitions observed for Ga(In)NAs alloys (Shan et al., 1999). Subsequently, it was extended to explain the electronic band structure in other HMAs, including III-N diluted with group V atoms (Wu et al., 2004; Alberi et al., 2007a; Alberi et al., 2007b; Levander et al., 2010), dilute bismides (Alberi et al., 2007a; Alberi et al., 2007b; Polak et al., 2015), II-VI diluted with O (Welna et al., 2014; Welna et al., 2015; Yu et al., 2002; Yu et al., 2003), and ZnO diluted with group VI atoms (Ting et al., 2015; Welna et al., 2017). $\text{GaN}_{1-x}\text{As}_x$ is best suited for presenting the BAC model, because on the same material the anticrossing effect can be shown in the conduction band (CB) as well as in the valence band (VB). Moreover, it was the most extensively studied material in the context of BAC model.

Fig. 10 shows the electronic band structure of $\text{GaN}_{1-x}\text{As}_x$ obtained within the BAC model for $\text{GaN}_{1-x}\text{As}_x$ diluted with N (left panel) and As (right panel). In the regime of $\text{GaN}_{1-x}\text{As}_x$ diluted with N (i.e., $1-x < 0.05$), a resonant level corresponding to N atoms is located above the CB minimum of the GaAs host. The interaction between N-related and CB states is modeled using the perturbation theory described by the following Hamiltonian:

$$H_{\text{BAC}} = \begin{pmatrix} E_{\text{CB}}(k) & C_{\text{NCB}}\sqrt{1-x} \\ C_{\text{NCB}}\sqrt{1-x} & E_{\text{N}} \end{pmatrix}, \quad (3)$$

where x is the mole fraction of substitutional N atoms. E_{N} is the energy of N-related states (s -like in this case) and $E_{\text{CB}}(k)$ is the energy dispersion of the CB of the GaAs host, both with respect to the top of the valence band of the host, and C_{NCB} is a constant that describes the interaction between N-related and CB states. For dilute-N $\text{GaN}_{1-x}\text{As}_x$ alloy, these parameters are: $C_{\text{NCB}} = 2.7$ eV and $E_{\text{N}} = 1.65$ eV (Shan et al., 1999; Wu et al., 2002).

Two highly non-parabolic subbands, $E_{-}(k)$ and $E_{+}(k)$, are formed due to the band anticrossing interaction between N-related and CB states. The k -vector dispersion of these subbands is given by Eq. (4):

$$E_{\pm}(k) = \frac{1}{2} \left[E_{\text{N}} + E_{\text{CB}}(k) \pm \sqrt{[E_{\text{N}} - E_{\text{CB}}(k)]^2 + 4C_{\text{NCB}}^2(1-x)} \right]. \quad (4)$$

In the regime of $\text{GaN}_{1-x}\text{As}_x$ diluted with As (i.e., $x < 0.05$), a resonant level corresponding to As atoms is located above the VB of the GaN host. The interaction between As-related (p -like states in this case) and VB states is modeled using a Hamiltonian analogous to the previous one:

$$H_{\text{simplified}}^{\text{N-rich}} = \begin{pmatrix} E_{\text{VB}}(k) & C_{\text{AsVB}}\sqrt{x} \\ C_{\text{AsVB}}\sqrt{x} & E_{\text{As}} \end{pmatrix}, \quad (5)$$

where x is the mole fraction of substitutional As atoms, E_{As} is the energy of As-related states, $E_{\text{VB}}(k)$ is the energy dispersion of the VB of the GaN host, and C_{AsVB} is a constant describing the interaction between the As-related and VB states. For dilute-As

Fig. 10 Repulsive anticrossing interaction of (a) localized N-states (2% N) with the extended GaAs conduction-band (CB) states, and (b) localized As-states (2% As) with the extended GaN valence-band (VB) states. Bands are plotted vs the vacuum level.

GaN_{1-x}As_x alloy, these parameters are: $C_{AsVB} = 0.75$ eV and $E_{As} = 0.62$ eV (Wu et al., 2004). In this case, highly non-parabolic subbands are formed in the VB and they are given by Eq. (6):

$$E_{\pm}(k) = \frac{1}{2} \left[E_{As} + E_{VB}(k) \pm \sqrt{[E_{As} - E_{VB}(k)]^2 + 4C_{AsVB}^2 x} \right]. \quad (6)$$

In general, the band anticrossing interaction in the VB is more complex because of complexity of the VB. In the case of GaN_{1-x}As_x diluted with As, the full Hamiltonian for the band anticrossing interaction in the VB should be composed of three subbands typical of host material (WZ GaN in this case) and three states associated with the isovalent dopant (As in this case) with the p_x , p_y , and p_z symmetry. A Hamiltonian with three valence subbands and one As-related level (all states with spin up and spin down) was developed and subsequently applied to study of the electronic band structure for GaN_{1-x}As_x (Alberi et al., 2007a; Alberi et al., 2007b). Also, the full-valence BAC Hamiltonian with three host subbands and three resonant levels has been developed for dilute bismides, i.e., ZB III-V alloys with a few percent of Bi atoms with the band anticrossing interaction between the Bi-related and VB states (Gladysiewicz et al., 2015).

BAC parameters (the position of resonant level relative to the CB (or VB) states and the interaction constant between the resonant level and CB (or VB) states) are needed to describe the electronic band structure within the BAC model. These parameters were quite intensively studied for dilute nitrides, dilute oxides, and dilute bismides. It was observed that the interaction constant is smaller for alloys in which the difference in electronegativity of isovalent atoms is smaller, which is consistent with the assumptions of the model (Polak et al., 2015; Shan et al., 1999; Wu et al., 2002). The position of the resonant level relative to the VB changes according to the position of the host VB to the vacuum level.

Strain and band gap engineering

In optoelectronic devices, band gap engineering is necessary to obtain the desired semiconductor heterostructure. As shown, it can be obtained by alloying semiconductors, but an equally important element is the strain engineering, which is an indispensable element of the deposition of layers on a given substrate. The lattice constant of the deposited layer usually has a different crystal lattice constant than the substrate, which in this case determines the lattice constant in the plane of the heterostructure and generates strains in the deposited layers. These strains modify the electronic band structure including the energy gap.

Considerable limitations in band engineering exist for elemental semiconductors (i.e., group IV) due to a few materials (in fact Si, Ge, and Sn) and the small number of possible alloys. In addition, these materials, without Ge_{1-x}Sn_x, have an indirect energy gap, which limits their use in optoelectronics. Therefore, III-V compounds are key materials in such semiconductor devices as light emitting diodes and lasers. Due to alloying different III-V compounds it is possible to tune the band gap and grow low dimensional heterostructures with a desired quantum confinement for electrons and holes, but their band gap tuneability is also quite strongly limited because of earlier mentioned strain. It comes from the fact that all III-V heterostructures have to be grown on a given substrate with a given crystal lattice constant (GaN, GaAs, InP or GaSb).

With a few exceptions (e.g., AlSb, GaSb and InAs, which are known as 6.1 Å family compound) the different crystal lattice constant of binary compounds limits the content of III-V alloys, which can be deposited on a given substrate with the thickness below the critical thickness. In addition, the built-in compressive (or tensile) strain strongly influences the electronic band structure and thereby limits the band gap tuning. The problem of strain engineering is illustrated in the sketch in Fig. 11. For a given alloy the band gap narrows with the increase in the crystal lattice constant according to previously discussed chemical trend for III-V alloys, which can be realized by mixing group III (or group V) atoms for regular alloys. Such a layer can be deposited on the X substrate with the lattice constant a_X greater than the lattice constant of the AC compound (a_{AC}) and smaller than the lattice constant of the BC compound (a_{BC}). Then, the layer with a lattice constant lower than a_X is under tensile strain, and the layer with a lattice constant greater than a_X is under compressive strain, as long as the thicknesses of these layers are below the critical thickness. Exceeding the critical thickness is not desirable because it generates dislocations and leads to deterioration of optical/electrical properties of the deposited layers. Therefore, strains significantly limit the range of alloy compositions of a given layer that can be deposited on a given substrate. Moreover, the strains narrow the range of the energy gap change due to its modification, compare the thin and thick lines in Fig. 11: compressive strains open the energy gap, while tensile strains narrow the energy gap.

The introduction of additional semiconductor compounds (AD and BD) for alloying allows to obtain a quaternary alloy that can be lattice matched to a specific substrate, see Fig. 11 (b). Such layers play a very important role in semiconductor devices. For substrates that are crucial in the optoelectronic devices (GaAs, InP and GaSb), it is possible to obtain quaternary layers lattice matched to the GaAs, InP and GaSb substrate within regular alloys: GaInPAs/GaAs, GaInPAs/InP, AlGaInAs/InP and GaInAsSb/GaSb.

Quaternary alloys allow for a more independent tuning of the band gap and the strain than the ternary alloys in which these two quantities are related. Apart from the energy gap and strain, the band gap discontinuity is another parameter that needs to be tuned in quantum heterostructures. This is especially important for quantum wells where the quantum confinement must be precisely matched to the desired emission or other requirements. Such engineering is possible with quinary alloys but is still challenging in terms of control of the alloy composition.

In general, the band gap engineering is easier if we have more compounds with different energy gaps and band gap discontinuities that can be alloyed together. Therefore, III-V semiconductors have great potential in this area. In addition to regular alloys,

Fig. 11 (a) Sketch of energy gap dependence on the crystal lattice constant for unstrained ternary $A_{1-x}B_xC$ alloy (thin blue line) and a layer of $A_{1-x}B_xC$ alloy deposited on X substrate (thick blue line). (b) Unstrained (thin lines) and strained (thick lines) ternary $A_{1-x}B_xC$ (blue lines) and $A_{1-x}B_xD$ (green lines) alloys and $A_{1-x}B_xC_{1-y}D_y$ alloy lattice matched to X substrate.

HMAs also have great advantages as some of them offer new features in band gap engineering. One of them, related to strain, is a different relationship between the energy gap and the crystal lattice constant as shown in Fig. 12. For a regular alloy (in this case $GaP_{1-y}As_y$ or $Ga_{1-x}In_xAs$) reducing the crystal lattice constant leads to the opening of the energy gap (this is a well-known chemical trend discussed earlier). For HMAs ($GaN_{1-y}As_y$ in this case), the narrowing of the energy gap along with the reduction of the crystal lattice constant can be achieved, see Fig. 12. Such a relation between the energy gap and the crystal lattice constant is not observed for regular alloys and, therefore HMAs offer new possibilities in band gap engineering. In this case, it is possible to obtain $Ga_{1-x}In_xN_{1-y}As_y$ lattice matched to GaAs with an energy gap much narrower than the GaAs energy gap, see Fig. 12.

Van der Waals semiconductors and their alloys

The best known representative of van der Waals crystals is graphite, which can be exfoliated into a single layer (graphene layer). It is worth emphasizing here that graphite is an allotropic form of carbon, which was previously discussed in the diamond form and where the carbon is tetrahedrally coordinated with sp^3 hybrid atomic orbitals. In graphite, carbon is trigonally coordinated and covalently bounded with sp^2 hybrid atomic orbitals in the plane, see Fig. 1. In each plane (layer), the carbon atoms are arranged in a honeycomb lattice and the individual layers are called graphene. The p -orbitals that do not hybridize between atoms from adjacent layers are oriented perpendicular to these planes. Therefore, bonding between layers is relatively weak van der Waals bonds, which allows the layers to be easily separated by mechanical exfoliation. Silicon or germanium in the graphite structure is not stable, but graphene equivalents realized by silicon (silicene) or germanium (germanene) atoms are more and more often considered and studied (Liu et al., 2019; Acun et al., 2015; Molle et al., 2018).

Another quite well explored van der Waals crystals are transition-metal dichalcogenides (TMDs) with MX_2 formula, where M is a transition-metal atom (Mo or W) and X is a chalcogen atom (S, Se, or Te), see Fig. 13. They are layered crystals in a hexagonal structure consisting of sixfold-bonded metal atoms sandwiched between two threefold-bonded chalcogenide atoms with a covalent interaction between atoms within a layer and a van der Waals interaction between layers.

The relation between the band gap and the crystal lattice constant for MoS_2 , $MoSe_2$, $MoTe_2$, WS_2 , and WSe_2 compounds is shown in Fig. 13 with energy gaps taken from Kopaczek et al., 2022. In this case the chemical trends previously discussed for tetrahedrally

Fig. 12 The relation between the energy gap and the crystal lattice constant for regular alloys ($\text{GaP}_{1-y}\text{As}_y$ and $\text{Ga}_{1-x}\text{In}_x\text{As}$) and $\text{GaN}_{1-y}\text{As}_y$, which is a HMA, together with the lattice matched $\text{Ga}_{1-x}\text{In}_x\text{N}_{1-y}\text{As}_y$ HMA.

Fig. 13 Arrangement of atoms and relationship between the energy gap and the crystal lattice constant for MoX_2 and WX_2 compound semiconductors.

coordinated semiconductor crystals can be easily recognized, i.e., the band gap narrows with the increase in the crystal lattice constant. In addition, it has been observed that the preferred crystallographic structure changes from 2H to 1T going to heavier atoms: MoTe_2 occurs in 2H and 1T structure, while WTe_2 prefer 1T structure (Zhou et al., 2022) is semi-metal and is not shown in Fig. 13. The dependence of the energy gap on the composition for $\text{Mo}_{1-x}\text{W}_x\text{X}_2$ and $\text{MoS}_{2(1-x)}\text{Se}_{2x}$ alloys can be described by Eq.(2) as for regular III-V alloys (Wu et al., 2014; Kopaczek et al., 2021). This issue is currently being researched for both bulk crystals and single layers.

Perovskites and their alloys

Organic-inorganic hybrid perovskites adopt crystal structure with general formula of ABX_3 , where A is organic cation, B is the metal element, and X is the halide element. The hybrid perovskite methylammonium lead halides (MAPbX_3) is composed of corner-sharing PbX_6 octahedrons with the organic cation MA^+ occupying the voids in the three-dimensional inorganic framework, see Fig. 14. The energy gap of MAPbX_3 compounds is dominated by the PbX_6 octahedrons, while the MA^+ cation contribution is little. This means that the electronic band structure of MAPbX_3 can be tuned by changing the Pb-X bond length and Pb-X-Pb angle in the inorganic framework. This can be achieved by changing X from Cl through Br to I. By replacing atoms with a small valence radius with atoms with a large valence radius, the crystal lattice constant increases and the energy gap decreases as shown in Fig. 14. This relationship is a well-known chemical trend observed for tetrahedrally coordinated crystals, i.e., IV, III-V and II-VI semiconductors. The dependence of the energy gap on the composition for $\text{MAPbCl}_{3(1-x)}\text{Br}_{3x}$, $\text{MAPbCl}_{3(1-x)}\text{I}_{3x}$ and

Fig. 14 Arrangement of atoms and relationship between the energy gap and the crystal lattice constant for MAPbX₃ compound semiconductors.

MAPbBr₃(1-x)I_{3x} alloys can be described by Eq.(2) as for regular III-V alloys, but is still being investigated. In addition, it is worth emphasizing here that these compounds and their alloys occur in different crystallographic structures depending on the temperature (orthorhombic, tetragonal and cubic).

Conclusion

In summary, the electronic band structure for group IV semiconductors as well as III-V and II-VI semiconductors have been well studied and understood so far. The same chemical trends, i.e., the narrowing of the energy gap with the increase of the crystal lattice constant, can be observed for the groups of semiconductor materials occurring in the same crystallographic structure. Semiconductor alloying is essential to obtain materials with the desired performance, and this topic has also been extensively researched over the past decades and is quite well understood at the moment, but many alloys are still unexplored, especially HMAs. In general, alloying is easily achieved for similar crystals, i.e., crystals that crystallize in the same structure and are composed of isovalent atoms of similar electronegativity and valence radius. Then, the crystal lattice constant of such an alloy and many parameters related to mechanical properties can be linearly interpolated, and the parameters related to the band structure, including the energy gap, can be described by a quadratic interpolation with a bowing parameter describing deviations from linearity. For regular alloys, the bowing parameter is relatively small in relation to the energy gap value and increases for HMAs. However, for many HMAs, the band gap can no longer be described in terms of the quadratic approximation with a reasonable bowing parameter (i.e., smaller value of bowing than the energy gap), and in this case the BAC model is very useful for estimating the energy gap. The chemical trends that have been observed for tetrahedrally coordinated semiconductors are also present for van der Waals crystals and perovskites, which have been known for a long time but which should rather be classified as a new generation of materials for use in semiconductor devices. In this case, it can also be expected that some of these alloys will behave like regular alloys and some like HMAs. According to the chemical trends and in analogy to dilute oxides (II-VI HMAs), MX₂ (M = Mo or W; X = S, Se, or Te) diluted with oxygen can be HMAs within van der Waals crystals. Within perovskites, MAPbX₃ diluted with fluorine can be HMAs. But first, such crystals must be obtained, and this can be a challenge. In general, the synthesis of homogeneous HMAs with a low defect concentration is challenging and was not discussed in this chapter. The further development of semiconductor alloys (both known and new) will be driven by their demand in specific semiconductor devices and may largely focus on improving their homogeneity and controlling their electrical conductivity through appropriate doping, i.e., issues that were not addressed in this chapter. Next emerging directions in semiconductor heterostructures go beyond the mixing of semiconductor compounds from the same family and are associated with the growth of III-V materials on silicon and combining different groups of materials, i.e., depositing van der Waals crystals on III-V materials or combining van der Waals crystals with perovskites. In these types of directions, strain engineering does not play a significant role, and among the promising materials for applications, there are those that are tolerant to defects. Unlike III-V semiconductors, the defect tolerant semiconductor compounds and alloys can be produced using cheaper methods than molecular beam epitaxy or metalorganic vapor-phase epitaxy, which are required for the growth of III-V (or II-VI) heterostructures for optoelectronic devices. Therefore, the next generation of cheaper semiconductor devices can be based on these types of compounds and alloys. The chemical trends presented and discussed in this chapter should also work for semiconductor compounds and alloys with non-tetragonal atom coordination as shown for van der Waals crystals and perovskites.

Introduction

Intermetallic compounds provide a rich and diverse resource to study the relationships among chemical composition, atomic structure, electronic structure, and physical properties. Since the majority of chemical elements are ‘metals,’ even with thermodynamic constraints, the numbers, types, and complexity of intermetallic compounds are immense, which is readily apparent in *Pearson’s Handbook of Intermetallic Phases*. An understanding of the electronic states of an intermetallic compound can provide insights into the chemical bonding factors influencing composition and structure as well as the electronic underpinnings of its electrical and magnetic behavior. Experimental determination of electronic states, largely through photoelectron spectroscopy, demands pure samples, which can be a challenge to obtain because most metals react readily with oxygen. On the other hand, there is a great deal of effort on quantum mechanical calculations of the electronic structure. This article provides an overview of a comprehensive general picture of electronic states in intermetallic compounds, including brief descriptions of specific examples.

What are Intermetallic Compounds?

At first glance, the answer seems obvious: intermetallic compounds are chemical substances formed when two or more metallic elements combine with a definite composition. They typically have small heats of formation (ca. – 50 to –10 kJ mol^{–1}) when compared to salts and polymeric compounds (ca. – 500 to –100 kJ mol^{–1}), but frequently show finite ranges in composition for a single phase, called homogeneity widths. Some melt congruently without decomposition into different phases, while many decompose peritectically into a liquid phase and another solid with a different composition. Concerning their structures, the various metal constituents are usually ordered in different sublattices, each with its own distinct population of atoms. In this way, elements of differing sizes or electronegativities can combine to give new compounds. Often, the corresponding structures are distinct from those of the component elements, but this is not necessary.

One important aspect of the definition is the combination of ‘metallic’ elements. Chemical substances are classified as either metals or nonmetals, and many periodic tables of the elements include a zigzag line, with metals on the left and nonmetals on the right. A closer examination of the elements near this line reveals numerous unusual trends in structural and physical properties, such that in addition to the classification as normal metals, semiconductors and insulators, there are also ‘metametals’ and ‘semimetals.’ The different classification schemes for ‘metals’ show the following characteristics.

1. Normal metals (alkali, alkaline earth, noble (Cu, Ag, Au) and many ‘transition metals’):
 - (a) Ductile materials based on close-packed structures with high coordination numbers (12, 8 + 6) and high symmetry (cubic or hexagonal).
 - (b) Typically electropositive elements with low first ionization potentials and low electron affinities.
 - (c) Increasing electrical resistivities with increasing temperature; values ~1 μΩ cm.
 - (d) Temperature-independent paramagnetism. Examples include the alkali, alkaline earth, noble (Cu, Ag, Au), and many ‘transition metals.’
2. Metametals (Zn, Cd, Hg, Ga, In, Tl, Pb, and β-Sn as assigned by W. Klemm in the 1950s):
 - (a) Ductile materials based on nearly close-packed structures with moderately high symmetry (hexagonal and orthorhombic) and coordination numbers (6 + 6; 4 + 8).
 - (b) Higher electronegativities than normal metals (except Pt and Au).

[☆]Change History: February 2015. G.J. Miller, added one additional current reference.

- (c) Increasing electrical resistivities with increasing temperature; values $\sim 10 - 100 \mu\Omega \text{ cm}$.
 - (d) Temperature-independent diamagnetism. W. Klemm in the 1950 s assigned Zn, Cd, Hg, Ga, In, Tl, Pb, and β -Sn to this category.
3. Semimetals (Sb, Bi, Te, Po):
 - (a) Brittle materials based on network structures with low densities.
 - (b) Larger electronegativities than most normal metals and metametals.
 - (c) Decreasing electrical resistivities with increasing temperature; values $\sim \text{m}\Omega \text{ cm}$.
 - (d) Temperature-independent diamagnetism.

properties and giving each element the number in the sequence – the Pettifor number ($P\#$). This scheme has proved quite useful in separating different structural classes – in the periodic table, it nicely separates the different classifications of metals.

Furthermore, the term ‘intermetallic compound’ is occasionally used interchangeably with ‘alloys,’ but they do differ from conventional metal alloys in a number of important ways. Conventional alloys consist basically of a disordered solid solution of two or more metallic elements with similar sizes and chemical characteristics. They do not have any particular chemical formula, and are best described as consisting of a base material to which certain percentages of other elements have been added. For example, type 304, a popular grade of stainless steel, has the composition Fe–18%Cr–8%Ni. An intermetallic compound, on the other hand, is based upon a definite atomic ratio, with a fixed or narrow range of chemical composition. Figure 2 shows the Al–Ni phase diagram as an example of a binary system showing solid solutions and intermetallic compounds.

Elements such as B, Si, Ge, P, As, and Se, themselves nonmetals, as well as C, when combined with metallic elements are considered to form ‘intermetallic compounds’ because their structures resemble those of other intermetallics, and they form with definite compositions. The elements H, N, O, S, and halogens are not considered to give intermetallic compounds, although numerous sulfides and some halides show a metallic character. The smaller elements, for example, H, B, C, N, and O can often occupy interstitial sites in intermetallic compounds, which greatly affect their mechanical, chemical, and physical properties.

The atoms in conventional alloys are linked through relatively weak interatomic interactions, often called ‘metallic bonds,’ with the atomic nuclei placed in a ‘gas’ of valence electrons that are able to move relatively freely, which explains their ductility, electrical conductivity, and temperature-independent paramagnetism. In contrast, chemical bonding in intermetallic compounds may show significant polar covalent character, which can produce strong interatomic interactions, brittle mechanical behavior, transport properties ranging from semiconducting to superconducting, and various magnetic interactions leading to complex magnetic structures. However, in intermetallic compounds whose mechanical and electronic properties resemble those of alloys, the individual elements tend to occupy different positions within the crystal lattice. This condition, which is referred to as ‘ordering,’ often leads to abrupt changes in the physical properties of the material.

Figure 2 Al–Ni phase diagram and structures of various intermetallic compounds in this binary system. Light-colored spheres are Al; dark-colored spheres are Ni.

Classifying Electronic States in Intermetallic Compounds

One useful tool for assigning compounds into different categories is a van Arkel–Ketelaar triangle, which maps compounds according to two related chemical coordinates using an electronegativity scale based upon the average one-electron valence shell energy of the ground-state free atom, called the configuration energy (CE). In this map, shown in Figure 3, the horizontal coordinate is the average CE of the constituents, while the vertical coordinate is the difference, so that metallic substances lie to the left. The transition from metallic to nonmetallic behavior involves either increasing electronegativity in general, or increasing electronegativity difference between constituents. Since CE represents the average energy of a valence electron, CE correlates with the separation between the energies of the valence s and p orbitals, and so influences the way atoms will interact with one another. Low CE values give small $E_{np} - E_{ns}$ values and broad, frequently overlapping energy bands. In many cases, the electronic states for these systems behave like nearly free electron states. Moreover, valence d orbitals are important for the properties of transition elements and valence f orbitals for the rare-earth and actinides – changes in the band filling of these orbitals affect the structure, cohesive energies, thermodynamic properties, and magnetic character. Unlike valence s and p orbitals, the valence d and f orbitals give narrower energy bands, and have more atomic-like character in compounds. The $4f$ orbitals in rare-earth elements and their compounds are generally localized, while the $5f$ orbitals in actinides have a greater role in chemical bonding.

This qualitative picture implies a variation in the description of states from a nearly free electron (NFE) model to a tight-binding (TB) model. In NFE, the electronic states are treated as linear combinations of plane waves (the eigenstates for a free electron gas). The arrangement of positively charged atomic nuclei creates a potential that perturbs the free electron states. The extension of this approach is toward pseudopotentials, which makes the valence states orthogonal to the core atomic states. In TB, the electronic states are treated as linear combinations of atomic orbitals (the one-electron eigenstates of free atoms). Pseudo-potential methods as well as TB methods have been used to study metals and semiconductors – the TB methods lead to useful chemical insights by virtue of starting from atoms, and have provided valuable understanding even for systems in which NFE would be entirely appropriate.

To calculate the electronic densities of states (DOS), multi-electron terms in the total electronic energy may be treated either in the local density approximation (LDA) or in the local spin density approximation (LSDA) and the one-electron terms can be treated scalar relativistically. For the heavier elements, spin–orbit coupling should also be considered. For many ground-state properties (structure, cohesive energy, magnetism, and electronic transport), the LDA is quite effective. Numerous recipes exist for calculating the exchange and correlation terms. An especially valuable analysis of the DOS is through the crystal orbital Hamilton population (COHP) analysis, which allows states to be identified according to the bonding, nonbonding, or antibonding character of the interatomic interactions (COHP values are, respectively, less than, equal to, or greater than zero).

Experimental determination of electronic states can be carried out by photoelectron spectroscopy, which is a surface-sensitive technique. de Haas–van Alphen effect gives information about the Fermi surface in reciprocal space, but demands quite pure

Figure 3 The van Arkel–Ketelaar triangle based on configuration energies of the atomic components.

samples. Hall effect measurements provide information about the charge carriers. Other methods, such as specific heat and magnetic susceptibility studies on metals, can give values of the DOS at the Fermi level.

Electronic Interactions Between Different Metallic Types

An examination of Pearson's *Handbook of Intermetallic Phases* shows that the predominant classes of intermetallic compounds involve the following combinations of metallic elements using the designations in Figure 1: (1) A'-T'; (2) A-M and A-M'; (3) T-T'; (4) (T, T')-(M, M'); and (5) (A, A')-(T, T')-(M, M'). Very few examples exist for (A, A')-(A, A'), (M, M')-(M, M'), (A, A')-T, T-T, and T'-T'. This observation guides our emphasis to the important electronic interactions: (1) *d-d*; (2) *d-sp*; and (3) *sp-sp*.

The two most important factors influencing the electronic DOS are the relative energies of the atomic orbitals of the different constituents and the strengths of the interatomic orbital interactions leading to bandwidths, that is, band dispersion. Energy gaps, pseudogaps, and peaks in the DOS arise from these two fundamental characteristics. Since the majority of intermetallic compounds show metallic properties, the 'perfect' screening of conduction electrons means that there is essentially no charge transfer between different elements. Therefore, the 'common band' model is most appropriate for analyzing the DOS. Additional factors include composition and the coordination environments surrounding each element in a structure.

d-d Interactions

Intermetallic compounds involving just transition metals are technologically important due to their mechanical, chemical, and physical properties. Some of the strongest chemical bonds in condensed phases are found among these compounds, as measured by their cohesive energies. The electronic states of transition metals exhibit a partially occupied, narrow valence *d* band that lies near the bottom of a broad valence *s* or *sp* band. Since the valence *d* electrons remain relatively tightly bound to their parent atoms, the appropriate method to treat the *d-d* electronic interactions is the TB model. When different transition metals combine to give an intermetallic compound, the primary effect is the way the different *d* orbitals interact – the valence *s* or *sp* band remains broad, and contributes to the chemistry and physics of these materials by adjusting the extent of filling of the *d* bands. The *d-d* orbital interactions break down into σ , π , and δ types of orbital overlap, with σ overlap the greatest and δ overlap the lowest (Scheme 1).

The *d-d* π interactions are important for the structural variation of the transition metals in the 4*d* and 5*d* periods (h.c.p.–b.c.c.–h.c.p.–f.c.c.) (b.c.c. – body-centered cubic; f.c.c. – face-centered cubic; h.c.p. – hexagonal close-packed). These overlaps affect the shape of the *d*-band DOS – see Figure 4, which compares the DOS curves for a b.c.c. and f.c.c. 4*d* transition metal. The local environments in the two structures both have cubic symmetry, and the local *d* orbitals are split into e_g and t_{2g} levels. The local coordination environment of the b.c.c. structure creates a region of low, nonzero DOS values close to six valence *s* and *d* electrons between two regions of high DOS values. This region of low DOS is called 'quasigap' or 'pseudogap.' COHP analysis of the DOS shows that *d-d* bonding states are below the pseudogap while antibonding states lie above. On either side of six valence *s* and *d* electrons, close-packed (h.c.p., f.c.c.) structures are preferred. Trends in effective nuclear charge and occupation of bonding versus antibonding states help explain the trend that across a period of transition metals, the *d* bandwidth slightly increases and then sharply decreases while the *d* band center steadily decreases. These trends have profound influences on the states of transition metal intermetallics.

When two different transition metals form an intermetallic compound, the shape of the DOS will depend on both the structure and the electronic characteristics of the component elements. In the case of disordered alloys AB, the 'common band' model is appropriate for understanding heats of formation and trends in cohesive energies with respect to metals A and B (see Scheme 2). In this model, the valence *d* band of each transition metal is characterized by an energetic center (ϵ_M^0 ; $M=A, B$) a bandwidth (W_M^0 ; $M=A, B$), and band filling (N_M electrons; $0 \leq N_M \leq 10$; A, B; indicated by the shaded regions in Scheme 2). The resulting *d* band for the disordered alloy AB has a bandwidth given by $W_{AB} = \bar{W} [1 + 3(\Delta\epsilon/\bar{W})^2]^{1/2}$ ($\bar{W} = (W_A^{AB} + W_B^{AB})/2$; $\Delta\epsilon = \epsilon_A - \epsilon_B$; $\epsilon_A^0 - \epsilon_B^0$), band filling of $\bar{N} = (N_A + N_B)/2$. To construct this *d* band for the alloy AB, there is 'renormalization' of the average band energies ($\epsilon_M^0 \rightarrow \epsilon_M$; $M=A, B$) to keep local charge neutrality (i.e., no effective charge transfer) and the bandwidths ($W_M^0 \rightarrow W_M^{AB}$; $M=A, B$) due to changes in atomic volumes from the element to the alloy. In this *d* band, states below the band center $\bar{\epsilon}$ are mostly from metal B, while those above $\bar{\epsilon}$ are mostly from metal A (as indicated by the dashed line for the AB band). Therefore, electrons flow from A to B because B is more electronegative than A ($\epsilon_A^0 < \epsilon_B^0$), but also flow back from B to A through orbital overlap in alloy AB.

The common band model predicts that the most stable intermetallic compounds and alloys would arise from combinations of transition metals at opposite ends of the transition metal series and that the highest cohesive energies exist for AB systems with

Scheme 1

Figure 4 DOS and nearest-neighbor COHP analysis for the b.c.c. and f.c.c. structures of a typical $4d$ transition metal. The energy zero corresponds to six valence s and d electrons. In the COHP curves, metal–metal bonding states occur for $-\text{COHP} > 0$; antibonding states for $-\text{COHP} < 0$.

Scheme 2

$\bar{N} : 5$. Specifically, the cohesive energy for AB, $U^{\text{AB}} : -k\bar{N}(10 - \bar{N})W_{\text{AB}} + cW_{\text{AB}}^2$ (k, c are positive constants) has an attractive part related to band filling and a repulsive part related to the number of nearest neighbors, which is proportional to the square of the bandwidth. The expression for the heat of formation of AB is more complicated, but takes the form $\Delta H_f^{\text{AB}} : f(\bar{N}(10 - \bar{N}))(\Delta N)^2$ where $\Delta N = N_B - N_A$. Negative heats of formation occur for $\bar{N}$ between 3.33 and 6.67 electrons per atom. For an intermetallic compound AB, with an ordering of A and B atoms, this model is appropriate for adjacent elements (small $\Delta\epsilon$ values), but is less appropriate as this energy difference increases. For larger $\Delta\epsilon$ values, a pseudogap can open in the DOS, as seen in Figure 5 for TiFe, which adopts the CsCl-structure type. The DOS curves of Ti and nonmagnetic Fe show features as expected – a lower band center and a narrower bandwidth for Fe. In TiFe, the d bandwidth is wider than that for either element, but the shape shows a pseudogap at the center of the d -band and the Fermi level falls in this pseudogap. States below this pseudogap are mostly Fe-orbitals, while those above are mostly Ti-orbitals. Nevertheless, TiFe is not held together by ‘ionic’ forces because the perfect screening of the valence electrons negates any charge transfer – there is a ‘renormalization’ of the energies of each transition metal. The DOS shows aspects of the local coordination, but the principal factor creating the pseudogap in TiFe is the energy difference between the band centers of Ti and Fe. COHP analysis of the DOS of TiFe shows that states below the Fermi level are Ti–Fe bonding; those above are Ti–Fe antibonding. The homonuclear Fe–Fe and Ti–Ti interactions are weaker (longer distances) and bonding below the Fermi level, but

Figure 5 Left: DOS curves of nonmagnetic Fe, Ti, and TiFe. The shaded regions in the DOS of TiFe are Fe states. Right: Assignment of the peaks in the DOS of TiFe into local e_g and t_{2g} levels as well as COHP analyses for Ti-Fe, Ti-Ti, and Fe-Fe near-neighbor interactions.

the crossover from bonding to antibonding interactions does not occur at the pseudogap. Therefore, another aspect of the pseudogap in intermetallic compounds is the creation of bonding states below the gap and antibonding states above. Therefore, many stable intermetallic compounds show low DOS values at the Fermi level, which can be accounted for by certain metal-metal interactions through a COHP analysis of the DOS.

Trends in the features of DOS curves depend on the types of interactions, the relative magnitudes of orbital overlaps and atomic electronegativities. Figure 6 shows the trends in DOS and COHP curves for TiRu, TiRh, and TiPd, which follows the structural trend b.c.c.-f.c.c.-h.c.p., but with ordered arrangements of metals. A pseudogap is noticeable in all cases for six states per formula, although it is less clear in the TiRh and TiPd cases. TiRu adopts the CsCl structure with eight nearest-neighbor Ti-Ru interactions and 12 s nearest-neighbor homonuclear (Ti-Ti and Ru-Ru) contacts. In TiRh and TiPd, there are six heteroatomic (Ti-Rh or Ti-Pd) and six homoatomic (Ti-Ti, Rh-Rh, Pd-Pd) nearest-neighbor contacts, which interferes with the pseudogap. Additionally, the bandwidths become narrower as the 4d metal becomes more electronegative. Again, there is no charge transfer between Ti and the 4d metal, in accordance with the common band model.

If the DOS value at the Fermi level is sufficiently high, then the structure is susceptible to an electronic distortion, which will perturb the electronic states near the Fermi level and lower the total electronic energy. This effect can happen in one of two ways: (1) a structural distortion, as in VIr (which distorts away from the cubic CsCl-structure type); or (2) ferromagnetism. For ferromagnetism to occur, the local exchange energy must also be sufficiently large, and this occurs for some of the 3d elements, which have the smallest spatial extent. The Stoner criterion states that ferromagnetism is preferred when $IN(E_F) > 1$, where I is the intra-atomic exchange energy (chemists will think about the so-called 'pairing energy' – the energy penalty in putting two electrons

Figure 6 DOS and COHP analyses of the 3d-4d intermetallic compounds, TiRu, TiRh, and TiPd. Shaded regions of the DOS are states from the electronegative metal (Ru, Rh, Pd). Fermi levels are indicated by the dashed lines.

into the same atomic orbital) and $N(E_F)$ is the value of the DOS at the Fermi level. Since $N(E)$ is typically inversely proportional to the bandwidth W , when either intra-atomic or inter-atomic interactions lead to narrow bands, and the local exchange is sufficiently large, ferromagnetism frequently occurs – the 3d elements Fe, Co, and Ni as well as compounds involving Mn are especially susceptible.

d-(*s*)*p* Interactions

Intermetallic compounds between transition metals and main group metals display interesting magnetic, superconducting, mechanical, and structural properties. In most cases, the electronic states near the Fermi level of these compounds are dominated by the *d* orbitals of the transition metal component. Their electronic structures arise from two dominant factors: (1) the expansion of the transition metal lattice due to the insertion of the main group (*sp*) element; and (2) the interaction between the valence *d* bands on the transition metal with the *sp* bands of the main group element. Three categories occur (see Figure 7): (1) where the *d* levels lie much deeper in energy than the main group atom (e.g., PdLi); (2) where the opposite is true (e.g., 'PdF'); and (3) the intermediate case where the two are of similar energy (e.g., PdB). In the first two cases, there is a rather weak interaction between the two sets of orbitals. The transition metal *d* band is narrower than in the pure metal, as a result of stretching the metal lattice to accommodate the nonmetal. These two cases do differ, however: (a) PdF is quite 'ionic,' involving charge transfer from metal *d* states to the low-lying fluorine-located bands - note that the Fermi level drops from the top of the *d* band; (b) PdLi utilizes the common band

picture, but the Fermi level rises above the top of the Pd 4*d* band – note the significant contribution from Li valence states in the region of the Pd 4*d* band. A similar example is the case of CsAu, which is an unusual example of a red, transparent, semiconducting intermetallic compound – its photoelectron spectrum shows a band gap of 2.6 eV. The case of PdB is most interesting because strong mixing occurs between the two sets of orbitals. These bands can be separated into bonding, non-bonding, and antibonding regions between the metal and nonmetal. Changes to the DOS will occur on composition – the strongest interactions will typically involve transition metal–main group metal, but the DOS will depend on the concentration of different orbitals. In transition metal-rich compounds, the metal *d* band will dominate and be broadened by T–T interactions; in main group metal-rich compounds, the metal *sp* bands may now become apparent.

One factor governing the atomic arrangements in intermetallic compounds is the relative strengths and concentrations of heteroatomic (between different elements) and homoatomic (between identical elements) interactions. As the molar concentration of the transition metal increases, the *d* band will become wider and may adjust its position depending on the relative electronegativity of the main group metal. For example, in the Ni–Al system, one can see the influence of composition on the DOS in Figure 8 for three different examples. As there is an increased dilution of Ni in Al, the Ni 3*d* bands become narrower and pull away below the Fermi level.

Main group elements show extensive structural diversity as the number of valence *s* and *p* electrons changes. For less than the half-filled band situation, for example, among group 13 elements like Al and Ga, clusters based on octahedra, square pyramids, and tetrahedra are common. Such clusters can be used to visualize structures through condensation of vertices, edges, or faces and create new understanding of electronic and bonding characteristics, as in transition metal trialuminides, MAl₃ (M = rare-earth element, Ti, Zr, Hf, V, Nb, Ta). As the number of valence electrons increases in this family, the network of Al-based polyhedra changes from octahedra to square pyramids. The DOS shows a pseudogap at the Fermi level (see Figure 9 for TaAl₃ as an example), which is largely influenced by the bonding states of the Al polyhedra. Nevertheless, M–Al orbital interactions also split the 5 *M d* levels into two sets (*e_g* below *t_{2g}*), which also contributes to the observed pseudogaps in the DOS curves as well as the preferred structures and electronic properties. In fact, such compounds are called *d*–*p* covalent intermetallics – COHP analysis of the DOS in TaAl₃ shows maximum bonding character for both Al–Al and Ta–Al interactions.

Pseudogaps occur in intermetallics for reasons based on structure and atomic electronegativities. Another important growing class of compounds is the set of half-metallic ferromagnets, of which the ‘semi-Heusler alloys’ represent significant examples (‘semi-Heusler’ alloys, ABX, consist of cubic closest packed X atoms with B atoms in all octahedral holes and A atoms ordered in one-half of the tetrahedral holes of the close-packed array of X ‘Heusler’ alloys, A₂BX, have all tetrahedral holes filled). These compounds are cubic intermetallic phases combining main group metals (Sn and Sb) with two different transition metals (one early T – Ti, Zr, Hf, V, Nb; one late T’ – Fe, Co, Ir, Ni, Pt). Their electronic properties, and therefore, their electronic states, depend strongly on the number

of valence electrons: 18-electron examples such as TiCoSb are diamagnetic semiconductors, 17-electron examples are metallic and Pauli paramagnetic, whereas 19- or 22-electron examples show half-metallic ferromagnetic behavior. Half-metallic ferromagnetism originates when the nonmagnetic electronic structure is susceptible to splitting of the majority and minority spin DOS, and the Fermi level falls in an energy gap for either spin, as seen in the LSDA DOS for VCoSb , a 19-electron example, in Figure 10 (VCoSb is a weak ferromagnet because there is an energy gap at nine states for both spin states; a half-metallic ferromagnet shows an energy gap just in the minority spin band, as seen in NiMnSb). The nonmagnetic DOS at the Fermi level for 19 electrons (VCoSb) is large, and is susceptible to ferromagnetism within the Stoner criterion. The lowest energy valence orbitals are from Sb, then from Co, finally from V since the atomic electronegativities increase from V to Co to Sb. The gap in the DOS at 18 valence electrons originates from these valence orbitals, the symmetry of the local coordination environments and metal–metal interactions: (1) Sb has four valence orbitals and the five Co $3d$ orbitals make nine low-lying orbitals to be filled for 18 electrons; (2) the tetrahedral coordination of Sb around Co and octahedral coordination around V keep the Co $3d$ levels low and split by a small amount; and (3) V–Co orbital interactions help to keep a band gap at 18 electrons, which accounts for the properties of TiCoSb . In these examples, the gap opens through d – d interactions between the two different transition metals – note the strength of early-late d – d interactions, just as mentioned in an earlier section.

sp–*sp* Interactions

Due to the widely different electronegativities of these elements, theoretical determinations of their electronic states range from NFE through pseudopotentials to TB models. There are three principle types of interactions (see Figure 1): A–A, A–M, and M–M. A–A interactions are best modeled by the NFE because the active metals have the lowest $E_{np} - E_{ns}$ values and diffuse valence atomic orbitals. The more electronegative main group metals (M) require pseudopotential or TB models because $E_{np} - E_{ns}$ increases and the valence atomic orbitals become contracted. In intermetallic structures, coordination environments surrounding A-type elements involve several atoms and often resemble densely packed structures, whereas those around M-type elements show lower coordination numbers and some directional bonding character. As the electronegativity difference between main group elements increases, the DOS develops a structure, that is, peaks and pseudogaps (or gaps), as seen for the three hypothetical compounds: ‘ NaMg ,’ ‘ NaAl ,’ and ‘ MgAl ’ in Figure 11. A–M compounds constitute an important class of compounds called ‘polar intermetallics,’ in which orbital interactions within the network of electronegative M atoms typically maximizes bonding interactions. If the local structure around the M atoms obey classical valence rules, then these compounds are called ‘Zintl phases.’ Subtle electronic effects can arise from valence d orbitals: for alkaline-earth elements, there can be contributions of $(n-1)d$ orbitals to ns bands, especially under pressure, whereas for Cu, Ag, Au, Zn, Cd, and Hg, $(n-1)d$ orbitals can hybridize with the valence ns and np bands.

Hume–Rothery ‘electron compounds’ are formed between noble metals and *sp* metals – in these systems, the noble metal d band is filled, so that the dominant orbital interactions will be *sp*–*sp* interactions. There are five phases that Hume–Rothery identified as controlled by electron count: (1) h.c.p. (three subcategories: ζ ($c/a = 1.633$), ε ($c/a = 1.55 - 1.58$), and η ($c/a = 1.77 - 1.78$)); (2) f.c.c.; (3) b.c.c./CsCl-type (β -brass); (4) β -manganese; and (5) γ -brass. TB models account for the structural variations very well, which attests to the importance of orbital interactions influencing these structures. Analysis of the DOS and band structure for CuZn reveal, however, that optimized metal–metal bonding is not the driving force here (Figure 12). As Pettifor and co-workers have shown, the

Figure 10 Nonmagnetic (top) and LSDA (bottom) DOS for VCoSb, a semi-Heusler alloy. The dashed line indicates the Fermi level – note the bandgap in the minority spin states. Black regions are V orbitals; gray regions are Co orbitals; white regions are Sb orbitals.

structural trend is driven by van Hove singularities in the DOS (places where the band structure has zero slope, which occur at the bottom or top of energy gaps at Brillouin zone boundaries). The band structure shows that the valence d bands are well below the Fermi level, but, nevertheless, hybridize with the NFE-like sp bands. Numerous quasicrystalline and approximant systems (Li–Cu–Al, Mg–Zn–Al) have been interpreted as similar ‘electron compounds,’ but the NFE gives little structural chemical information.

Zintl phases involve combinations of electropositive and electronegative main group metals, for example, LiAl, in which the electronegative element forms a structure based on the octet rule if one assumes that the electropositive element donates all of its valence electrons. The octet rule demands that eight bonding or nonbonding valence electrons surround main group (sp) elements

Figure 11 DOS curves for NaMg, NaAl, and MgAl, and the shaded regions are states from the more electropositive element. The dashed line shows a free electron type DOS.

in stable structures. Thus, the structure of LiAl has a diamond network of four-bonded Al atoms, which is formulated as 'Al⁻,' isoelectronic with Si. The DOS of Zintl phases show either a gap or pseudogap at the Fermi level with bonding states within the electronegative metal network fully occupied (Figure 13). So, 'classical' Zintl phases are defined as follows: They are compounds that (1) contain an alkali or alkaline-earth metal and an electronegative main group element that is a metal, semimetal, or smallgap semiconductor; (2) are electronically balanced or close-shell compounds, that is, the number of valence electrons provided by the constituents equals the number of electrons needed for two-center, two-electron covalent bonds in the structure; (3) are semiconductors or poor conductors; (4) are either diamagnetic or show a very weak temperature-independent paramagnetism; and (5) are typically brittle.

Among the *sp* class of intermetallic compounds, the Hume–Rothery phases behave as normal metals while Zintl phases are typically semiconductors. 'Polar intermetallics' represent an intermediate class of compounds, formed between active metals with electronegative metals, but the DOS shows a pseudogap near the Fermi level. COHP analysis of the DOS indicates optimized bonding in the electronegative component and the active metal behaves like a cation, but typically does not donate its full

Figure 12 Energy bands and DOS for CuZn (β -brass structure). Shaded region in the DOS comes from valence s and p orbitals of Cu.

Figure 13 Structure, DOS, and Al-Al COHP analysis for LiAl. Shaded region is Al orbitals.

complement of valence electrons. The structure of the electronegative component, however, cannot be explained by the octet rule – there is substantial delocalized bonding. The most prolific example of this structural class is the BaAl_4 -type, whose structure is adopted by hundreds of examples involving transition metals as well (Figure 14). There are numerous subcategories based on how different elements are arranged: ThCr_2Si_2 , CaBe_2Ge_2 , BaNiSn_3 are three common examples.

In polar intermetallics where the active metal is among the rare-earth elements, the predominant interatomic interactions involve $6s$ and $5d$ valence orbitals of the rare-earth with the valence s and p orbitals of the main group element. If there is significant hybridization between the valence $4f$ orbitals and the sp orbitals of the main group metals, then interesting properties may arise, for example, ‘heavy fermion’ behavior. Valence fluctuations in the rare-earth element are also important for this situation, while a

Figure 14 Structure, DOS, and Al-Al COHP analysis for BaAl_4 . Shaded region is Al orbitals.

Figure 15 Band structure, DOS, and Al-Al COHP analysis for CeAl_3 .

COHP analysis of the sp - sp interactions shows nearly maximum bonding within the main group framework. This is frequently observed for Ce, but is also possible with Yb, with an f band that mixes with states near the crossover from bonding to antibonding characteristics (Figure 15).

Conclusion

Describing the electronic states of intermetallic compounds requires an understanding of the distinct electronic structures of the various types of metallic elements. These elements combine in many different ways, and the nature of these interactions can be

addressed using different quantum mechanical approximations, varying from the NFE model to the TB theory. Fundamental factors controlling the electronic states include: (1) composition, (2) relative electronegativities of elements, which control the relative valence orbital energies, and (3) coordination environments (structure and atomic arrangements). Depending on the nature of these interactions, conducting properties can vary from metallic to semiconducting while magnetic properties can range from itinerant ferromagnetism to diamagnetic. Valence fluctuations and heavy fermion behavior are possible for rare-earth compounds, and $5f$ orbitals contribute to the chemical bonding interactions in actinide compounds.

Introduction

The electronic and magnetic properties of transition-metal compounds are imparted by the d and/or $4f$ electrons of the transition-metal compounds. (This article does not cover the actinides.) The outer s and p electrons of these compounds, which are primarily responsible for the chemical bonding, are split by an energy gap E_g between filled anionic bonding bands and empty cationic antibonding bands. The s and p states contribute to the electronic and magnetic properties of the transition-metal compounds through covalent mixing with the d and/or $4f$ orbitals.

The $4f$ electrons always form localized $4f^n$ configurations as on a free atom unless a $4f^n/4f^{n+1}$ redox couple is overlapped by the Fermi energy (the electrochemical potential) ε_F of a partially filled broadband of itinerant-electron states, in which case hybridization of the $4f$ and itinerant electron states creates massive itinerant electrons called heavy fermions. The d electrons, on the other hand, may be localized, itinerant, or vibronic depending on the relative strengths of the intra-atomic and the inter-atomic interactions and how the competition between these two is modulated by disturbances of the periodic potential of a crystalline array of the like atoms or by elastic and thermal energies.

The intra-atomic energies are those of the free transition-metal atom as modified by covalent mixing with the ligand orbitals. The Hamiltonian for the electrons of a free atom has three components of descending magnitude:

$$H = H_o + U + \lambda L \cdot S \quad [1]$$

where H_o corresponds to the energy of a single electron moving in the field of a nucleus of effective charge $+(Z - \sigma_l)e$. The atomic number Z is reduced by a screening σ_l of the other atomic electrons; σ_l depends on the orbital angular momentum quantum number l of the electron being screened from the nuclear charge $+Ze$. The energy U is the electrostatic energy required to add an electron to a configuration of d or $4f$ electrons and is a measure of the separation of successive ionization energies; $U = J_c - J_{ex}$ has two components, a Coulombic repulsion J_c and a quantum-mechanical correction J_{ex} that keeps electrons of parallel spin in different orbitals by the Pauli exclusion principle. The last term in eqn [1] gives rise to the multiplet splitting of a $^{2S+1}L_J$ term, where Russell–Saunders coupling applies to the d^n and $4f^n$ configurations of total angular momentum quantum number $J = L + S$; L and S are the total orbital and spin angular-momentum quantum numbers. The atomic magnetic moment is

$$\mu_A = -g_L J \mu_B \quad [2]$$

where g_L is the Landé spectroscopic splitting factor and μ_B is the Bohr magneton.

In a solid, the ‘interatomic interactions’ depend on the expectation value for an electron to transfer to a neighboring atom without a change of energy as a result of the perturbation H' of the free-atom potentials by their proximity to one another:

$$b_{ij} \equiv \langle \psi_i, H' \psi_j \rangle \approx \varepsilon_b (\psi_i, \psi_j) \quad [3]$$

[☆]Change History: July 2015. J. Goodenough made changes throughout the text.

where ε_b is a one-electron energy and (ψ_i, ψ_j) is the overlap integral of the initial and final atomic orbitals occupied by the electron. The subscripts refer to atoms at R_i and R_j in the crystal. Electron transfers between states of the same energy are treated in the first-order theory ($\Delta E \sim b$) and between states separated by an energy Δ or U in the second-order theory ($\Delta E \sim b^2/\Delta$ or b^2/U). The tight-binding bandwidth for electrons transferring between like atoms of a periodic array of crystallographically equivalent sites with $U=0$ is given by

$$W_b \approx 2zb \quad [4]$$

where z is the number of like nearest neighbors and b is the b_{ij} for these nearest neighbors. The crossover from localized-electron behavior (intra-atomic interactions dominant) to itinerant-electron behavior (interatomic interactions dominant) occurs where

$$W_b \approx U \quad [5]$$

This crossover is known as the ‘Mott-Hubbard transition.’

The localized electrons occupy an n -electron configuration d^n or f^n located at a single transition-metal atom and having an energy corresponding to that of a redox couple d^{n-1}/d^n or f^{n-1}/f^n . Successive redox couples are separated by an energy U . The itinerant electrons, on the other hand, belong equally to all the like atoms of a periodic array on crystallographically equivalent sites; they are described by a band of single-electron energies of width W_b that is occupied by electrons in accordance with the Pauli exclusion principle and the Fermi–Dirac distribution function. In this limit, a $U < W_b$ is assumed to be screened by the other electrons so as to make $U=0$. For narrower bandwidths W_b , this ‘electronic Fermi-gas model’ must be modified by the introduction of a finite $U < W_b$. This problem can be treated by mass-renormalization techniques that transform the electrons into a ‘quasiparticle Fermi liquid.’

Impurities, lattice defects, and substitutional dopants all disturb the periodic potential of an array of transition-metal atoms in a solid. These disturbances narrow the effective width of W_b by introducing localized states (Anderson localized states) at the top and bottom of a band of itinerant-electron states above and below, respectively, a ‘mobility edge.’ If the Fermi energy ε_F lies in the energy range of localized states, the conductivity is described as ‘variable-range hopping’ between these localized states.

The Mott–Hubbard transition may not be smooth as originally assumed; it is a first order transition that gives an abrupt volume change where the electrons transform from itinerant to localized character; the localized electrons give a larger equilibrium M–O bond length than itinerant electrons. The first-order character of this transition generally introduces the coexistence of two different equilibrium bond lengths at crossover. In the latter case, the resulting bond-length fluctuations at high temperatures order at lower temperatures so as to give long-range-ordered atomic clusters, a charge-density wave (CDW), or a charge-ordered (CO) state in order to minimize the elastic energy. The elastic energies associated with local site deformations are also minimized by cooperative ordering. Examples of local site distortions are displacements of a cation from the center of symmetry of its interstice, cation clustering, valence disproportionation, and an orbital ordering that either lowers the local site symmetry or increases its deformation from cubic symmetry.

The electronic and magnetic properties of the d electrons of transition-metal compounds are strongly influenced not only by whether they occupy states with $W_b < U$, $W_b \approx U$, or $W_b > U$ but also by order–disorder transitions. Order–disorder transitions are driven by the heat $T\Delta S$ associated with disorder. Heat also drives disordering of long-range magnetic order, which removes magnetostriuctive and/or exchange-strictive deformations of the crystal symmetry; and by increasing the crystal volume, it may induce changes from antiferromagnetic to ferromagnetic coupling, that is, ‘exchange inversion,’ below a long-range magnetic ordering temperature.

In mixed-valent compounds, the transport properties also depend critically on whether the time $\tau_h \approx \hbar/W_b$ for an electron to hop from one atom to a like nearest neighbor is $\tau_h > \omega_R^{-1}$, $\tau_h \approx \omega_R^{-1}$, or $\tau_h < \omega_R^{-1}$, where ω_R^{-1} is the period of an optical-mode vibration that would trap the charge carrier at a single site as a ‘small dielectric polaron.’

In the following sections, the metal–ligand interactions are first introduced to construct ligand-field orbitals having the same symmetries as the atomic d orbitals. The interactions between the ligand-field orbitals of neighboring metal atoms are then discussed for $W_b < U$, $W_b \approx U$, and $W_b > U$. Next, the significance of the radial extension of the ligand-field orbitals and the location of the Fermi energy relative to the edges of the broad filled and empty bands is presented in the context of illustrative examples of the varied phenomena that are encountered in these materials.

Metal–Ligand Interactions

Redox couples f^n or d^n

The description of the outer electrons of a primarily ionic transition-metal compound begins with a point-charge model; the electrostatic Madelung energy E_M of that model generally lowers the most energetic ligand (anion) p orbitals an energy ΔE_p below the lowest unoccupied redox energy of the transition-metal atom. A $\Delta E_p \leq 0$ may pin the antibonding redox couple at the top of the bonding ligand- p band; in this case, the redox couple can commonly be treated by the molecular-orbital or band theory. However, back electron transfer from the anion across an energy $\Delta E_p > 0$ to an empty d or f orbital on the cation is treated in the second-order perturbation theory to give a stabilization energy $\Delta E \sim (b^{ca})^2/\Delta E_p$ of occupied bonding states that tends to compensate for the loss in electrostatic Madelung energy E_M of the point-charge model; the empty antibonding d or f orbitals of the d^n or f^n configuration are

correspondingly destabilized by an energy ΔE . As noted in eqn [3], the expectation value for a back electron transfer depends on the cation–anion overlap integral in b^{ca} and, therefore, on the relative symmetries of the interacting orbitals. Consequently, symmetry arguments are used to develop a parametrized second-order description of the ‘ligand-field orbitals’; these orbitals take account of the interactions between the d or f electrons and the anions. Next, the metal–metal, metal–anion–metal, and/or metal–anion–anion–metal interactions are introduced; the ligand-field orbitals either remain localized or become itinerant depending on the relative strengths of these inter-atomic interactions and the intra-atomic energy U_{eff} for the atomic ligand-field orbitals.

Rare-Earth $4f^n$ Configurations

The rare-earth $4f$ electrons are tightly bound to their atomic nucleus and are largely buried within a $5s^2 5p^6$ core-electron cloud that prevents strong overlap of the $4f$ orbitals with the orbitals of the neighboring ligands. Consequently, the $4f^n$ configurations remain localized with a $U_{\text{eff}} \gg W$, and any splitting of the individual f -orbital energies by interaction with the ligands is smaller than the intra-atomic multiplet splittings by $\lambda L \cdot S$. Therefore, the localized $4f^n$ configurations in a compound retain their atomic magnetic moment $\mu_A = g_L \mu_B$ of eqn [2]. Nevertheless, the interactions with the ligands contribute, along with the ‘magnetic dipole–dipole $4f^n$ interactions,’ to the weak ‘spin–spin interatomic exchange’ interactions between $4f^n$ configurations that are responsible for long-range magnetic order at low temperatures and also to the ‘magnetocrystalline anisotropy’ that introduces a preferred orientation of μ_A relative to the crystallographic axes and an associated ‘magnetostriction’ below the magnetic-ordering temperature. Long-range ordering of the spins S induces long-range ordering of the orbital angular momenta L by the spin–orbit coupling $\lambda L \cdot S$; and interactions with the ligands order the orbitals responsible for L , and therefore J , relative to the crystallographic axes and also induce the anion displacements responsible for the magnetostriction. Magnetostriction reflects the orientation of the atomic moments; ‘exchange striction’ reflects changes in the binding energy due to magnetic order and, therefore, reflects the symmetry of the long-range magnetic order.

The d -Block d^n Configurations

The five d orbitals of a free atom are degenerate, but with more than one electron or hole in a d^n manifold, the spin degeneracy is removed by the ferromagnetic direct-exchange interactions between electron spins in orthogonal atomic orbitals. The Pauli exclusion principle keeps electrons of the same spin in different d orbitals, which reduces the energy $U = J_c - J_{\text{ex}}$ by the intra-atomic exchange energy J_{ex} . These spin–spin exchange interactions produce the ‘Hund intra-atomic exchange field H'_{ex} ’ responsible for the Hund highest multiplicity rule for the free atom. The splitting between states of different spin for a given orbital will be designated Δ_{ex} .

The atomic orbitals f_m with azimuthal orbital angular momentum operator L_z , where $L_z f_m = -i\hbar \partial f_m / \partial \phi = \pm m\hbar f_m$ with $m = -l, \dots, +l$, have the angular dependencies for $l = 2$:

$$\begin{aligned} f_0 &\sim (\cos^2 \theta - 1) \sim [(z^2 - x^2) + (z^2 - y^2)]/r^2 \\ f_{\pm 1} &\sim \sin^2 \theta \exp(\pm i\phi) \sim [yz \pm izx]/r^2 \\ f_{\pm 2} &\sim \sin^2 \theta \exp(\pm i2\phi) \sim [(x^2 - y^2) \pm i2xy]/r^2 \end{aligned} \quad [6]$$

In an isolated octahedral site, the xy and $(yz \pm izx)$ orbitals only overlap the neighboring $O-2p_\pi$ orbitals while the $[(z^2 - x^2) + (z^2 - y^2)]/r^2$ and $(x^2 - y^2)/r^2$ orbitals only overlap the $O-2s$ and $O-2p_\sigma$ orbitals. These two groupings of orbitals are distinguished by symmetry as a twofold-degenerate set of e orbitals and a threefold-degenerate set of t orbitals (Figure 1). The electron-transfer (resonance) energy integrals $b^{\text{ca}} \equiv (f_m, H' \phi_o) \approx \epsilon_{\text{mo}}(f_m, \phi_o)$ describing the expectation of a virtual charge transfer to an empty cation- d orbital from a same-symmetry sum of near-neighbor oxygen orbitals ϕ_o contain both an overlap integral (f_m, ϕ_o) and a one-electron energy ϵ_{mo} that are larger for σ -bonding than for π -bonding, that is, $b_\sigma^{\text{ca}} > b_\pi^{\text{ca}}$. Therefore, the antibonding e states of a σ -bond are raised higher by the energy $\Delta E \equiv (b^{\text{ca}})^2 / \Delta E_p$ than are the antibonding t states of a π -bond. The resulting cubic-field splitting is

$$\Delta_c = \Delta E_\sigma - \Delta E_\pi = \Delta_M + (\lambda_\sigma^2 - \lambda_\pi^2) \Delta E_p + \lambda_s^2 \Delta E_s \quad [7]$$

where Δ_M is a purely electrostatic energy that is small and of uncertain sign due to the penetration of the ligand- p^6 electron cloud by the cation- d wave function. The dimensionless covalent-mixing parameters are seen to be

$$\begin{aligned} \lambda_\sigma &= b_\sigma^{\text{ca}} / \Delta E_p, \quad \lambda_\pi = b_\pi^{\text{ca}} / \Delta E_p \\ \lambda_s &= b_s^{\text{ca}} / \Delta E_s \end{aligned} \quad [8]$$

in which ΔE_p and ΔE_s are the point-charge energy gaps between the degenerate atomic d orbitals and the ligand p and s orbitals, respectively. The second-order ligand-field wave functions are

Figure 1 Schematic crystal-field splitting of the d -state manifold of a transition-metal atom M in an octahedral site: (a) the one-electron d^1 configuration ($\Delta_{\text{ex}} = 0$); (b) the high-spin d^4 configuration, and (c) $\phi_{xy} = p_y^{(1)} + p_x^{(2)} - p_y^{(3)} - p_x^{(4)}$ that hybridizes with a d_{xy} orbital.

$$\begin{aligned}\psi_t &= N_\pi (f_t - \lambda_\pi \phi_\pi) \\ \psi_\sigma &= N_\sigma (f_e - \lambda_\sigma \phi_\sigma - \lambda_s \phi_s)\end{aligned}\quad [9]$$

where N_π and N_σ are normalization constants that constrain a one-electron state to contain a single electron.

Covalent mixing extends the ligand-field wave functions out over the anions, thereby reducing the electron–electron Coulomb energy U from its atomic value. For an octahedral-site cation, the ligand-field U is larger for electrons in the π -bonding t -manifold than for those in the σ -bonding e -manifold, that is, $U_t > U_e$.

As an aside, attention is drawn to the earlier crystal-field model in which the covalent component to the orbitals is neglected and the cubic-field splitting is simply parametrized as $\Delta_c = 10 Dq$. In this model also, the symmetry arguments distinguish the e and t manifolds in a cubic field or other splittings in lower symmetry, but the energy of the atomic d -state manifold is conserved and the crystal-field wave functions are simply the atomic wave functions f_m . Although this parametrized model allows interpretation of spectroscopies that measure the energy splittings, it fails completely to account for a lowered ligand-field U and for the interatomic interactions between like atoms that are responsible for long-range magnetic order where a $W_b < U_{\text{eff}}$ is found or for metallic conductivity where a $W_b > U_{\text{eff}}$ occurs.

If a d -block transition-metal ion occupies a tetrahedral site, similar considerations apply, but in this case the t orbitals have a larger orbital overlap and are raised higher in energy than the e orbitals by the cubic-field splitting Δ_c . Early crystal-field calculations give the relative values of Δ_c for the two cases as

$$\Delta_c(\text{tetrahedral}) \approx (4/9)\Delta_c(\text{octahedral}) \quad [10]$$

The d -electron Hamiltonian that includes the interactions with the ligand p and s orbitals is

$$H = H_o + J_c + (\Delta_c - J_{\text{ex}}) + (\lambda L \cdot S + \Delta_{\text{nc}}) \quad [11]$$

where Δ_{nc} is a noncubic component of the ligand-field splitting arising from a distortion of the site symmetry. Since the octahedral-site Δ_c is the same order of magnitude as the intra-atomic exchange energy Δ_{ex} , the d^4 – d^7 octahedral-site configurations may be either high-spin t^3e^1 , t^3e^2 , t^4d^2 , t^5e^2 where $\Delta_{\text{ex}} > \Delta_c$ or low-spin t^4e^0 , t^5e^0 , t^6e^0 , t^6e^1 where $\Delta_c > \Delta_{\text{ex}}$. Moreover, lowering of the site symmetry to tetragonal or orthorhombic may stabilize an intermediate-spin d^5 or d^6 configuration t^4e^1 or t^5e^1 , respectively. The larger the covalent mixing parameters $\lambda_\sigma > \lambda_\pi$, the smaller is Δ_{ex} and the larger is Δ_c . Moreover, the effective energy U_{eff} required to add an electron to a d^n manifold to make it d^{n+1} must take into account Δ_c as well as Δ_{ex} . For an octahedral-site cation, the U_{eff} for $n = 3$ and $n = 8$ is increased by Δ_c ; for $n = 5$ it is increased by Δ_{ex} if $\Delta_c < \Delta_{\text{ex}}$, and for $n = 6$ by Δ_c if $\Delta_c > \Delta_{\text{ex}}$.

By splitting the $m = \pm 2$ energies of eqn [6] into real ($x^2 - y^2$) and xy components, the operator $L_z = -i\hbar\partial/\partial\phi$ makes the azimuthal component of the orbital angular momentum imaginary, which means that the two e orbitals have $m = 0$ and the t manifold has orbitals with $m = 0, \pm 1$. It follows that configurations with zero, three, or six t electrons have their orbital angular momentum completely quenched (i.e., $L = 0$) to first order, and a spin-only atomic moment $\mu_A = gS\mu_B$ with $g \approx 2$ is a fair approximation.

The octahedral-site splitting may leave an orbital degeneracy, as occurs with high-spin $\text{Mn(III)}: t^3e^1$ or $\text{Cu(II)}: t^6e^3$, for example, or with high-spin $\text{Fe(II)}: t^4e^2$ or $\text{Co(II)}: t^5e^2$. In this case, the cubic site symmetry is unstable relative to a site distortion that removes the orbital degeneracy. This instability is known as a ‘Jahn–Teller distortion.’ In a crystal, a long-range-cooperative site distortion, that is, orbital ordering, minimizes the elastic energy that resists the distortion and lowers the space-group symmetry of the crystal. Cooperative Jahn–Teller distortions may transform isotropic 3D interatomic spin–spin interactions into a ferromagnetic interaction

Figure 2 Phase diagram of the spinel system $\text{Ni}_{1-x}\text{Fe}_x[\text{Ni}_x\text{Cr}_{2-x}]\text{O}_4$. Solid lines are tetragonal-cubic transition temperatures T_c . The O-orthorhombic phase may be a coexistence of tetragonal $c/a > 1$ and $c/a < 1$ phases. After Arnett, R.J., Wold, A, Rogers, D.B., 1964. *Journal of the Physics and Chemistry of Solids* 25, 161.

in one crystallographic direction and an antiferromagnetic interaction in another as is illustrated by LaMnO_3 (*vide supra*). Removal of a t^n -orbital degeneracy ($n = 1, 2, 4$, or 5) may either quench the orbital angular momentum or enhance it so as to gain a further splitting by the spin-orbit coupling $\lambda L \cdot S$; where σ -bonding electrons determine the magnetic order, a long-range collinear-spin configuration below a magnetic-ordering temperature introduces long-range order of the orbital angular momenta through $\lambda L \cdot S$ even where the concentration of orbitally degenerate cations is not large. Therefore, below a long-range magnetic-ordering temperature, distortions that enhance L and introduce a large magnetostrictive component scale with the concentration of cations with the t -orbital degeneracy. On the other hand, spin-orbit coupling prevents a cooperative ordering of the orbital momenta in the paramagnetic state of disordered spins; so cooperative distortions setting in above a magnetic-ordering temperature quench the orbital angular momenta. The two types of distortion can be distinguished as they have opposite sign. This situation is beautifully illustrated in **Figure 2** by the spinel system $\text{Ni}_{1-x}\text{Fe}_x[\text{Ni}_x\text{Cr}_{2-x}]\text{O}_4$ in which the tetrahedral-site $\text{Ni(II)}:e^4t^4$ are the Jahn-Teller ions.

The $\text{A}[\text{B}_2]\text{X}_4$ spinel structure consists of a close-packed-cubic array of anions X; the electrostatic Madelung energy is minimized by an ordering of the B cations on half of the octahedral sites and the A cations on tetrahedral sites of the interstitial space of the $[\text{B}_2]\text{X}_4$ array. The $\text{Ni}_{1-x}\text{Fe}_x[\text{Ni}_x\text{Cr}_{2-x}]\text{O}_4$ spinel also illustrates how the crystal-field splittings influence the site-preference energies of transition-metal cations. Sites that leave the higher-energy d orbitals empty are stabilized relative to those that leave them occupied. The Cr(III) ion has the configuration t^3e^0 in an octahedral site and e^2t^1 in a tetrahedral site, which gives it a strong octahedral-site preference. The high-spin Fe(III) ion with configurations t^3e^2 or e^2t^3 has little site preference. The Ni(II) ion, on the other hand, has an octahedral-site configuration t^6e^2 as against e^4t^4 in a tetrahedral site, which gives it a definite octahedral-site preference; but it is forced into the tetrahedral sites of the spinel by the Cr(III) ions, which have a stronger octahedral-site preference.

Ionic size also determines site preference. Smaller cations prefer tetrahedral sites; the d -block transition-metal cations of intermediate size, with the exception of Mn(II) and Cu(I) , prefer octahedral sites, and the larger rare-earth ions prefer a greater oxygen coordination. Where a smaller cation is forced by electrostatic Coulomb energies into an octahedral site, it may be unstable relative to a cooperative displacement from the center of symmetry of its interstice. Such a displacement introduces a local electric-dipole moment, and a cooperative parallel displacement gives a 'ferroelectric polarization' analogous to a 'ferromagnetic magnetization.' Therefore, such a displacement is referred to as a ferroelectric-type displacement even though the cooperativity may involve antiparallel displacements to give an antiferroelectric analogous to an antiferromagnet in which neighboring spins are aligned antiparallel. Lighter transition-metal cations of a given d -block can be stabilized in octahedral sites in their highest valence states, that is, with a d^0 configuration, but as the cation size decreases with increasing atomic number and formal valence state, the site preference changes from octahedral to tetrahedral. It is the ions with sizes at crossover to a tetrahedral-site preference that undergo ferroelectric displacements. In the $3d$ row, the Ti(IV) has an octahedral-site preference, but if the structure forces the Ti-O bond length to be greater than its equilibrium value, as occurs in the perovskite BaTiO_3 , the Ti(IV) ions may undergo a cooperative ferroelectric displacement. In BaTiO_3 , there are three successive cooperative displacements; on lowering the temperature, the Ti(IV) ions are displaced first toward one near-neighbor O^{2-} ion, then toward two, and finally toward three. The smaller V(V) cation, on the other hand, has a definite tetrahedral site preference, but when forced into an octahedral site as in V_2O_5 , it forms a short double bond V=O indicating molecular-orbital formation with both p_σ and the two p_π orbitals. The V(IV) may also form a $(\text{V=O})^{2+}$ vanadyl ion with an occupied d_{xy} orbital in the plane perpendicular to the d_{yz} and d_{zx} orbitals involved in the π molecular orbitals. In the $4d$ block, it is the Nb(V) ion that corresponds to the Ti(IV) and the Mo(VI) that corresponds to the V(V) . In the $5d$ series, the

W(VI) corresponds to the Ti(IV), and WO_3 is an antiferroelectric without a stretching of the W–O bond length by a counter cation as in BaTiO_3 .

Finally, it is noteworthy that where a transition-metal cation is deprived of its stable oxygen coordination, as occurs in the oxygen-deficient perovskite $\text{BaZr}_{1-x}\text{In}_x\text{O}_{3-0.5x}$, water may enter the oxygen vacancies at lower temperatures ($T \leq 400^\circ\text{C}$) to introduce OH^- anions and protonic conduction; the Zr(IV) ion is stable in eightfold oxygen coordination and definitely prefers a sixfold over the fivefold oxygen coordination just as the large Ba^{2+} ion prefers a 12-fold over the 11-fold coordination.

Metal–Metal Interactions

A measure of the strength of the interatomic cation–cation interactions is also the energy integral b_{ij} of eqn [3]. Direct cation–cation electron transfers b^{cc} between cations sharing a common site edge or face are distinguished from cation–anion–cation transfers b^{cac} that occur across an anion. The latter interactions are possible because the shared anion- p component (neglecting the smaller anion- s component for simplicity) of the ligand-field wave functions provides a significant overlap of the wave functions on neighboring cations. For a $(180^\circ - \phi)$ cation–anion–cation interaction, the electron transfer integrals b_σ^{cac} across a common anion- p_σ orbital must be distinguished from the smaller b_π^{cac} across a common anion- p_π orbital; in a 90° cation–anion–cation interaction, the electron transfer integral is $b_{\pi\sigma}^{cac}$ as it occurs across an anion- p orbital that σ -bonds with the d orbital on one cation and π -bonds with the d orbital on the other cation. With the ligand-field wave functions of eqn [9], these integrals become

$$b^{cc} = \varepsilon_{cc} (\psi_i, \psi_j) \quad [12]$$

which varies sensitively with the interatomic separation R ,

$$\begin{aligned} b_\pi^{cac} &\approx \varepsilon_\pi \lambda_\pi^2 \\ b_\sigma^{cac} &\approx \varepsilon_\sigma \lambda_\sigma^2 \cos \phi \\ b_{\pi\sigma}^{cac} &\approx \varepsilon_{\pi\sigma} \lambda_\pi \lambda_\sigma \end{aligned} \quad [13]$$

for a $(180^\circ - \phi)$ M-anion-M interaction. Two general conclusions follow. First, there is a critical cation–cation separation R_c below which the tight-binding bandwidth of eqn [4] is $W_b \approx 2zb^{cc} > U_{\text{eff}}$ and suppresses the localized-electron behavior to introduce the d electrons into either itinerant-electron states or cation-cluster molecular orbitals. Second, it is possible to have itinerant and localized electrons coexisting on the same atom. For example, $(180^\circ - \phi)$ cation–anion–cation interactions dominate in an AMO_3 perovskite, which has a simple cubic array of corner-sharing $\text{MO}_6/2$ octahedra with a larger A-site cation in the body center. A $b_\sigma > b_\pi$ and a $U_e < U_t$ allow a $W_\sigma > U_e$ or a mixed-valent $\tau_h < \omega_R^{-1}$ of e electrons in the presence of $W_\pi < U_t$ as is illustrated by metallic and magnetic SrFeO_3 and the metallic ferromagnet $\text{La}_{0.7}\text{Sr}_{0.3}\text{MnO}_3$.

The criterion for itinerant versus localized behavior in a mixed-valent compound is somewhat different from that in a single-valent compound. In a mixed-valent compound, electron transfer between atoms of a redox couple does not require overcoming an energy gap U_{eff} . However, the time $\tau_h \approx \hbar/W$ for an electron to transfer from one atom to another must be compared to the period $\omega_R^{-1} \approx 10^{-12}$ s of an optical-mode local vibration that traps a charge carrier. If the ligands have time to relax to an equilibrium position that distinguishes the smaller size of a cation of higher charge, then the stronger covalent bonding at the smaller site raises the energy of the empty antibonding orbitals above those of the occupied orbitals by ε_p as occurs with a redox couple in solution. The atomic relaxations thus self-trap a charge carrier, localizing it to a single site by introducing a small energy barrier between occupied and empty states. The self-trapped carriers are called ‘dielectric small polarons’; they move diffusively with a small activated mobility

$$\mu = (eD_0/kT) \exp(-\Delta G_m/hT) \quad [14]$$

in which $\Delta G_m = \Delta H_m - T\Delta S_m$ is the free energy required to equalize the energies of the orbitals on neighboring sites. This mobility contrasts with that for an itinerant electron:

$$\mu = e\tau_s/m^* \quad [15]$$

where τ_s is the mean free time between scatterings of the electronic charge carrier from aperiodicities in its periodic potential and m^* is the effective carrier mass. The crossover from polaronic to itinerant electronic behavior occurs where $\tau_h \approx \omega_R^{-1}$ or the polaron bandwidth is $W \approx \hbar\omega_R$. The polaronic bandwidth is reduced from the tight-binding bandwidth W_b of eqn [5] as

$$W = W_b \exp(-\lambda\varepsilon_p/\hbar\omega_R) \quad [16]$$

where $\lambda \sim \varepsilon_p/W_b$ is a measure of the strength of the electron–lattice coupling. The transition from polaronic to itinerant electronic behavior in a mixed-valent compound would generally occur where U_{eff} remains a little larger than W_b , but Coulomb interactions between the charge carriers may slow τ_h and induce charge ordering at higher charge concentrations. Moreover, local site distortions

at Jahn–Teller ions increase ε_p , which stabilizes polaronic behavior to larger values of W_b . Moreover, the virial theorem favors a first-order transition from localized to itinerant-electronic behavior, and the conditions under which the two types of crossover are found appear to be similar.

A first-order transition at $W_b \approx U_{\text{eff}}$ leads to bond-length instabilities; the two coexisting equilibrium bond lengths order at lower temperatures in a variety of ways to give such unusual phenomena as high-temperature superconductivity in copper oxides or a colossal magnetoresistance in manganese and cobalt oxides with a perovskite structure. At higher temperatures, bad-metal behavior with an unusual temperature dependence of the resistivity is found. As the temperature is increased, the bandwidth narrows and a smooth transition from itinerant to vibronic to polaronic behavior may be encountered.

The interatomic interactions of interest in the localized-electron regime $W_b < U_{\text{eff}}$ are the spin–spin interactions. The origin of the spin–spin interactions is in the quantum-mechanical exchange term J_{ex} entering U , so the spin–spin interactions are referred to as ‘exchange interactions.’

The most general form of the bilinear interatomic spin–spin coupling between localized spins at R_i and R_j is

$$V_{ij} = S_i \cdot K_S \cdot S_j + S_i \cdot K_A \cdot S_j \quad [17]$$

where K_S and K_A are symmetric and antisymmetric tensors. The first term reduces to an isotropic and an anisotropic component, $-2J_{ij}S_i \cdot S_j - 2S_i \cdot \Gamma \cdot S_j$, where $\Gamma \sim (\Delta g/g)^2$ represents a symmetric tensor and Δg is the deviation of the spectroscopic splitting factor from $g=2$. The antisymmetric term can be reduced to $-2D_{ij} \cdot S_i \times S_j$, where the Dzialoshinskii vector $D_{ij} \sim (\Delta g/g)$ has its axis determined by the crystal symmetry. A quantitative description of the magnetization $M(T)$ of a ferromagnetically aligned subarray may require inclusion of a biquadratic term $-2\gamma_{ij}(S_i \cdot S_j)^2$ where the magnitude of a cation–cation interaction varies sensitively with the cation separation R . In addition, the coexistence of localized and itinerant electrons (or molecular-orbital electrons) adds an additional term H_{ex}^D so the full phenomenological expression for the spin–spin interactions becomes

$$H_{\text{ex}} = H_{\text{ex}}^D - \sum_{ij} \left\{ J_{ij} S_i \cdot S_j + \gamma_{ij} (S_i \cdot S_j)^2 + D_{ij} \cdot S_i \times S_j + S_i \cdot \Gamma \cdot S_j \right\} \quad [18]$$

Measurement of the magnetic susceptibility $\chi_m \equiv M(T)/H_a$, where H_a is an applied magnetic field, reveals whether localized spins are present in a compound and the character of the dominant spin–spin interactions, which may be ferromagnetic ($J_{ij} > 0$) or antiferromagnetic ($J_{ij} < 0$). In the absence of localized spins, a compound may be diamagnetic ($\chi_m < 0$) or paramagnetic ($\chi_m > 0$), but χ_m is normally small and temperature independent in this case. However, superconductors exhibit a transition below their critical temperature from a $\chi_m > 0$ in the normal-metal state to a $\chi_m < 0$ in the superconductive state. Localized spins, on the other hand, give a temperature-dependent paramagnetic susceptibility $\chi_m(T) > 0$ that reflects not only the magnitudes of the atomic magnetic moments, but also the character of the spin–spin interactions. Moreover, the spin–spin interactions stabilize long-range magnetic order below a ferromagnetic Curie temperature T_c or an antiferromagnetic Néel temperature T_N . Several types of magnetic order are found.

‘Ferromagnetism’ refers to a parallel alignment of spins that gives a saturation magnetization $M_s(0) = \sum_i N_i \mu_{Ai}$ at $T=0$ K, where N_i is the number per unit volume of a transition-metal cation with moment μ_{Ai} and the sum is over all the different kinds of transition-metal cations that are present. The zero-field saturation magnetization $M_s(T)$ decreases with increasing temperature T , falling sharply to zero at $T=T_c$. In this case, the paramagnetic susceptibility obeys a Curie–Weiss law

$$\chi_m = C/(T - \theta) \quad [19]$$

where the Curie constant for a single spin species is

$$C = Ng^2 J(J+1) \mu_B^2 / 3k \quad [20]$$

and the Weiss constant $\theta = CW$ reflects the strength of the ferromagnetic interactions through the W of the internal Weiss molecular field WM that aligns the spins. Critical fluctuations above T_c makes the $\chi_m^{-1}(T)$ plot bend from linear as χ_m^{-1} approaches zero, which makes $T_c \leq \theta$.

‘Antiferromagnetism’ refers to a magnetic order that leaves the zero-field saturation magnetization $M(T)=0$ at all temperatures below a Néel temperature T_N . Néel antiferromagnetism consists of two like ferromagnetic subarrays aligned antiparallel to one another to give $M_s(T) = M_1(T) - M_2(T) = 0$. In this case, a $W < 0$ makes the Weiss constant of the Curie–Weiss law $\theta < 0$, and χ_m^{-1} is finite at $T_N > 0$. The antisymmetric term $D_{ij} \cdot S_i \times S_j$ of eqn [18] may cant the spins of an antiferromagnet to give a weak ferromagnetism. That this weak ferromagnetic component is not due to an impurity is beautifully illustrated by α -Fe₂O₃, which has the crystallographic and magnetic structure shown in Figure 3 at room temperature. The weak ferromagnetic component has been used in magnetic recording. In this structure, the Dzialoshinskii vector D_{ij} is oriented parallel to the c -axis, so spin canting occurs if the spins lie in the basal plane. Dipole–dipole interactions orient the spins in the basal plane of α -Fe₂O₃ in the temperature interval 250 K $< T < T_N = 953$ K; but below the Morin temperature $T_M = 250$ K, the spin orientation switches to the c -axis and the weak ferromagnetic component disappears abruptly.

‘Ferrimagnetism’ refers to an antiferromagnetic coupling of two ferromagnetic subarrays with magnetizations $M_1(T)$ and $M_2(T)$ where $M_s(T) = M_1(T) - M_2(T) \neq 0$ at all temperatures. Normally, $M_s(0) \neq 0$ in a ferrimagnet, but Fe₂(SO₄)₃ is an example where the

Figure 3 Antiferromagnetic spin configurations found in $\alpha\text{-Fe}_2\text{O}_3$ in the temperature interval $250\text{ K} < T < 953\text{ K}$ and the spin canting responsible for a weak ferromagnetic component σ_0 . After Shull, C.G., Strauser, W.A., Wollan, E.O., 1951. *Physical Review* 83, 333.

Fe(III) atoms of the two subarrays are in sites that are crystallographically inequivalent, so $M_s(T) \neq 0$ although $M_s(0) = 0$. The inverse paramagnetic susceptibility of a ferrimagnet is hyperbolic, approaching a Curie–Weiss law with $\theta < 0$ at high temperatures, but falling to zero at a Curie temperature $T_c > 0$. The most celebrated ferrimagnets are the ferros spinels, which have an antiferromagnetic coupling of tetrahedral-site and octahedral-site cations. Figure 4 illustrates the magnetic order in $\text{Fe}[\text{NiFe}]\text{O}_4$, where the octahedral-site cations are bracketed in the formula. In this case, the Fe(III) moments cancel one another and the net magnetization per formula unit is due to the nickel with $\mu_{\text{Ni}} \approx 2\mu_B$. Interestingly, substitution of Ni(II) by a nonmagnetic Zn(II) ion increases the magnetization because the Zn atoms prefer tetrahedral sites: $\text{Zn}_x\text{Fe}_{1-x}[\text{Ni}_{1-x}\text{Fe}_{1+x}]\text{O}_4$ has a magnetization per formula unit for small x of $\mu_{\text{mol}} = (2 + 8x)\mu_B$. A rhombohedral component of the ligand field at an octahedral site of the spinel structure splits the t manifold into a nondegenerate a_1 orbital ($m=0$) of lower energy and a twofold degenerate e_π -orbital manifold with $m = \pm 1$. Consequently, substitution of an Fe(II) for Ni(II) on the octahedral sites introduces mobile spins associated with the mixed iron valence, but it has little effect on the magnetocrystalline anisotropy. On the other hand, substitution of Co(II) for Ni(II) leaves the

Figure 4 Ferrimagnetic order of $\text{Fe}[\text{NiFe}]\text{O}_4$. After Hastings, J.M., Corliss, L.M., 1953. *Reviews of Modern Physics* 25, 114.

spinel an insulator but introduces a large magnetocrystalline anisotropy that increases linearly with the cobalt concentration as a result of splitting of the e_g -orbital degeneracy by $\lambda L \cdot S$.

'Spin-density wave (SDW)' refers to a noncollinear spin configuration that has a propagation vector q with a wavelength that may be either commensurate or incommensurate with a lattice period. Parallel alignment of near-neighbor spins in a ferromagnet or within a subarray of a Néel antiferromagnet or ferrimagnet may oppose weaker antiferromagnetic interactions between next-near-neighbor spins of the array. In this case, the crystal compensates either by changing its structure so as to weaken the antiferromagnetic interactions or by forcing the spins to become canted or, more commonly, to form an SDW. An SDW has an $M_s(T) = 0$ below T_N and is, therefore, antiferromagnetic. Figure 5 illustrates a simple spiral-spin (helical) configuration found in the rutile structure of MnO_2 . Canting of the octahedral-site spins is found in the tetragonal spinel $\text{Cu}[\text{Cr}_2]\text{O}_4$. Figure 6 illustrates the spiraling of this canted-octahedral-site configuration observed in $\text{Co}[\text{Cr}_2]\text{O}_4$.

'Metamagnetism' refers to the transformation of antiferromagnetic order to ferromagnetic order in a moderate applied magnetic field. For example, an SDW having ferromagnetic nearest-neighbor interactions is transformed at 50 K in MnP to a ferromagnet on which a weak SDW component is superimposed.

An analogous, but not strictly metamagnetic, situation is found in some double perovskites $\text{La}_2\text{M}_a\text{M}_b\text{O}_6$ where ordering of the M_a and M_b cations introduces ferromagnetic $\text{M}_a\text{--O--M}_b$ interactions within slabs, but leaves antiferromagnetic $\text{M}_a\text{--O--M}_a$ and $\text{M}_b\text{--O--M}_b$ interactions across antiphase boundaries. The ferromagnetic slabs are oriented antiparallel to one another in zero magnetic field, but the large magnetization of a slab allows a modest applied magnetic field to create a parallel orientation of the slabs except for spiral-spin interfaces centered at the antiphase boundaries.

'Frustrated systems' are those where strong antiferromagnetic interactions are unable to align all near-neighbor spins antiparallel to one another. This situation occurs, for example, in a close-packed plane or among the octahedral sites of a spinel. Frustration lowers the temperatures below which long-range magnetic order is found and leads to compromise spin configurations. In a close-packed plane with antiferromagnetic interactions between nearest neighbors, for example, the spins order at 120° rather than 180° with respect to one another.

'Spin glasses' are compounds containing ferromagnetic clusters in an antiferromagnetic matrix. Since the clusters are randomly distributed, the coupling between the clusters is frustrated, and the ferromagnetic regions assume random orientations below a spin-glass freezing temperature T_g . A 'cluster glass' consists of antiferromagnetic clusters in a ferromagnetic matrix.

Several processes contribute to the microscopic origins of the spin-spin interactions.

'Direct exchange' between spins in orthogonal orbitals is ferromagnetic; it is a 'potential exchange' as it does not involve electron transfer. The intra-atomic exchange splitting Δ_{ex} responsible for Hund's highest multiplicity rule for the free atom is a direct exchange.

Figure 5 Spiral-spin configuration propagating parallel to the c -axis of MnO_2 (oxygen coordination shown for only one cation; cf., Figure 9 for rutile structure). Turn angle between spins in successive (0 0 1) planes is $2\pi/7$. After Erickson, R.A., 1953. *Physical Review* 90, 779; Yoshimori, A., 1959. *Journal of the Physical Society of Japan* 14, 807.

Figure 6 Complex spiral-spin configuration found in the spinel $\text{Co}[\text{Cr}_2]\text{O}_4$. Spiral propagates along the $[1\ 1\ 0]$ direction. After Dwight, K., Manyuk, N., 1969. Journal of Applied Physics 40, 1156.

Interactions between spins on two atoms with overlapping orbitals is a ‘kinetic exchange.’ Two features are controlling, conservation of the spin angular momentum in the transfer and an angular dependence for electron spins having only the two directions α and β :

$$\alpha = \alpha' \cos(\theta/2) + \beta \sin(\theta/2) \quad [21]$$

where θ is the angle between localized spins on the two neighboring atoms. Therefore, the spin-independent electron-transfer integral b_{ij} of eqn [3] is replaced by a spin-dependent integral

$$t_{ij}^{\uparrow\uparrow} = b_{ij} \cos(\theta/2) \quad \text{or} \quad t_{ij}^{\uparrow\downarrow} = b_{ij} \sin(\theta/2) \quad [22]$$

‘Superexchange’ refers to interactions that require overcoming an energy barrier ΔE ; in this case, the electron transfer is virtual and is treated in a second- or higher-order perturbation theory. Two cases must be distinguished:

1. If the overlapping orbitals are each half-filled, electron transfer is constrained by the Pauli exclusion principle to be antiferromagnetic and

$$\Delta E_{\text{ex}}^S \approx -|t_{ij}^{\uparrow\downarrow}|^2 / U_{\text{eff}} = \text{const} + J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j \quad [23]$$

where $\Delta E = U_{\text{eff}}$ corresponds to the interaction in a single-valent compound; the $J_{ij} \sim (2b_{ij}^2)/4S^2 U_{\text{eff}}$ reduces to $2b^2/U_{\text{eff}}$ for nearest neighbors with $S = 1/2$.

2. If the overlapping orbitals are ‘half-filled and empty’ or ‘filled and half-filled,’ ΔE_{ex} favors a ferromagnetic charge transfer and

$$\Delta E_{\text{ex}}^S = \text{const} - J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j \quad [24]$$

with $J_{ij} \approx (2b_{ij}\Delta_{\text{ex}}/4S^2 U_{\text{eff}}^2)$ follows from a third-order perturbation theory.

With half-filled t^3 configurations, the $(180^\circ - \phi)t^3e^0 - \text{O} - t^3e^0$ interactions of the RCrO_3 (R =rare-earth) and $\text{Sr}_{1-x}\text{Ca}_x\text{MnO}_3$ perovskites are all antiferromagnetic as are the $t^3e^2 - \text{O} - t^3e^2$ interactions in the RFeO_3 perovskites. An antisymmetric $D_{ij} \cdot \mathbf{S}_i \times \mathbf{S}_j$ exchange term and/or cooperative rotations of the octahedral sites may cant the antiparallel spins by a few degrees to give a weak ferromagnetic moment. On the other hand, the double perovskite $\text{La}_2\text{NiMnO}_6$ with ordered Ni(II) and Mn(IV) exhibits ferromagnetic $\text{Ni(II)}:t^6e^2 - \text{O} - \text{Mn(IV)}:t^3e^0$ superexchange interactions. In the perovskite LaMnO_3 , the cooperative Mn(III) -site distortions of Figure 7 remove the e -orbital degeneracy of the t^3e^1 configuration and introduce $(180^\circ - \phi)$ $\text{Mn(III)}-\text{O}-\text{Mn(III)}$ superexchange interactions that are ferromagnetic in $(0\ 0\ 1)$ planes ($\lambda_\sigma > \lambda_\pi$) and antiferromagnetic between basal planes. Here also, a spin canting gives a weak ferromagnetic component. However, dilution of the Mn(III) ions in $\text{LaMn}_{1-x}\text{Ga}_x\text{O}_3$ introduces regions of orbital disorder at lower temperatures that are ferromagnetic in three dimensions because local site distortions induced by cooperative site rotations introduce an orbital mixing associated with tetragonal and orthorhombic site distortions. Where the ferromagnetic Curie temperature T_c of the orbitally disordered regions is higher than the Néel temperature

Figure 7 (a) Ordering of occupied e orbitals into (0 0 1) planes of LaMnO_3 and associated oxygen displacements. This cooperative orbital ordering is superimposed on a cooperative rotation of the $\text{MnO}_{6/2}$ octahedra (shown by arrows). Cooperative rotations bend the $(180^\circ - \phi)$ B–O–B bond angle in ABO_3 perovskites when the geometric tolerance factor $t \equiv (A - O)/\sqrt{2}(B - O) < 1$; $(A - O)$ and $(B - O)$ are the equilibrium $(A - O)$ and $(B - O)$ bond lengths. (b) Charge, orbital, and spin [up (+), down (–)] ordering in $\text{La}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$.

T_N of long-range antiferromagnetic order in the orbitally ordered matrix, an applied magnetic field stabilizes the orbitally disordered phase relative to the orbitally ordered phase to convert a spin glass into a ferromagnet.

‘Semicovalent exchange’ involves a two-electron transfer from a single anion- p orbital, one to each of the two cations on opposite sides in a $(180^\circ - \phi)$ cation–anion–cation interaction. Since the two transferred electrons have opposite spins, the rules for ferromagnetic versus antiferromagnetic coupling are the same as those for superexchange. A $U_{\text{eff}} \approx 0$ for the itinerant O- $2p$ electrons gives semicovallent exchange the form $-J_{ij}\mathbf{S}_i \cdot \mathbf{S}_j$ with $J_{ij} \approx (2b_{ij}^2/8S^2\Delta)$, where $\Delta = \Delta E_p$ is the ‘charge-transfer energy gap.’ To illustrate the significance of the semicovallent-exchange component to the total exchange, consider again the $(180^\circ - \phi)$ $t^3e^0 - \text{O} - t^3e^0$ interactions in the RCrO_3 and $\text{Ca}_{1-x}\text{Sr}_x\text{MnO}_3$ perovskites

$$\Delta E_{\text{ex}}^S \approx \sum'_{ij} \left(2b_{ij}^2/4S^2 \right) [1/U_{\text{eff}}] + (1/2\Delta) \quad [25]$$

Whereas the superexchange interactions treat only the π -bonding $t^3 - \text{O} - t^3$ interactions, semicovallent exchange also includes the σ -bonding interactions if a $(\Delta_{\text{ex}}/\Delta)^2$ multiplier is added. A $\Delta \leq U_{\text{eff}}$ in RCrO_3 and $\text{Ca}_{1-x}\text{Sr}_x\text{MnO}_3$ makes the semicovallent-exchange component dominant to give a total exchange-energy parameter $J_{\text{ex}} \sim \langle \cos^2 \phi \rangle$ (cf., eqn [13]). A $T_N \sim \langle \cos^2 \phi \rangle$ in an RMO_3 perovskite family signals localized-electron antiferromagnetism.

'Double exchange' occurs in mixed-valent transition-metal compounds in which a mobile spin has a $\tau_h < \omega_R^{-1}$ in the presence of localized spins. The mobile spin couples to the localized spin by the Hund intra-atomic exchange field to give a ferromagnetic interaction with a spin-dependent $t_{ij}^\uparrow = b_{ij} \cos(\theta/2)$ in the tight-binding formula of eqn [4], so

$$H_{\text{ex}}^D \approx -Nc(1-c)zb_{ij} \cos(\theta/2) \quad [26]$$

where Nc is the concentration of mobile charge carriers and $(1-c)z$ is the fraction of near-neighbor sites that are empty. Polaronic charge carriers do not introduce a double-exchange coupling as their τ_h is long compared to the time for a spin to relax to a disordered orientation. Equation [26] is the de Gennes formulation that he applied to the metallic ferromagnetic compositions of the system $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$; it assumes the coexistence of conductive ($\tau_h < \omega_R^{-1}$) σ -bond electrons in the presence of localized spins $S=3/2$ from the π -bond t^3 manifold. The original Zener formulation for double exchange in this system constrained the $\tau_h < \omega_R^{-1}$ to a $\text{Mn}^{3+}-\text{O}-\text{Mn}^{4+}$ two-manganese polaron that he assumed to move diffusively, but with no motional enthalpy ($\Delta H_m=0$). In fact, the electrons of e -orbital parentage undergo a crossover with increasing x from polaronic to itinerant-electronic behavior in this system. Figure 8 shows a small compositional and temperature range where the Zener model was thought to be applicable; it also reveals a discontinuous change in T_c at the transition from Zener to de Gennes double-exchange as predicted from the virial theorem for a transition from polaronic to itinerant-electron conduction. In fact, the ferromagnetism in the FV phase of Figure 8 has been shown to be the result of superexchange and orbital mixing as in the $\text{LaMn}_{1-x}\text{Ga}_x\text{O}_3$. An orbital ordering that lifts the degeneracy of the σ^* band of e -orbital parentage stabilizes the AFM phase of Figure 8; metallic, ferromagnetic (0 0 1) planes are coupled antiparallel to one another along the c -axis by $t^3-\text{O}-t^3$ superexchange. However, charge and orbital ordering in $\text{La}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$ traps the mobile charge carriers to give zigzag ferromagnetic chains coupled antiparallel to one another in the (0 0 1) planes, see Figure 7(b). The Mn^{3+} ions are confined to stripes of zigzag chains, as shown in the CO phase in Figure 8.

The spinel Fe_3O_4 has mixed Fe(II) and Fe(III) valence states on the octahedral sites, and an antiferromagnetic Fe–O–Fe superexchange interaction couples antiparallel the tetrahedral-site and octahedral-site spins to give a ferrimagnetic moment per Fe_3O_4 molecule of $\sim 4\mu_B$; the spins of the two Fe(III) ions cancel one another, and the ferromagnetic alignment of the octahedral-site spins reduces the spin-disorder scattering for motion of the minority-spin electrons in the presence of the localized majority-spin electrons to give a $\tau_h \approx \omega_R^{-1}$ between room temperature and a charge-order Verwey transition temperature $T_V \approx 120$ K. The mobile electrons give a ferromagnetic double-exchange interaction between the octahedral-site cations below room temperature. Fe_3O_4 represents another situation where itinerant and localized spins can coexist on the same atom. However, at higher temperatures spin-disorder scattering converts a $\tau_h \approx \omega_R^{-1}$ to a $\tau_h > \omega_R^{-1}$, and the mobile electrons become polaronic.

'Indirect exchange,' also known as Yaffet–Kittel–Kasuya–Yosida (YKKY) exchange, is a coupling of localized spins by a partially filled band of itinerant electrons; it is an extension of the de Gennes double exchange to a broad itinerant-electron band. Intra-atomic exchange stabilizes an itinerant-electron spin density parallel to the localized spin in the vicinity of the transition-metal atom, but this itinerant-electron spin density decreases at larger distances, reversing sign in a series of oscillations. If a neighboring localized spin is close enough to be overlapped by the parallel spin density, then the localized spins are coupled ferromagnetically; but if the antiparallel spin density overlaps the neighboring spins, they couple antiferromagnetically. The

Figure 8 Phase diagram of the system $\text{La}_{1-x}\text{Sr}_x\text{MnO}_3$. CFI = canted-spin type-A antiferromagnetic insulator (ferromagnetic (0 0 1) planes coupled antiparallel with orbital ordering of Figure 7(a)). FI, FV, and FM = ferromagnetic insulator, vibronic conductor (Zener polarons), and de Gennes metal, respectively. AFM = type-A antiferromagnetic metal. CO = charge-ordered phase. O' and O'' refer to different orbitally ordered orthorhombic phases, O^* to an orbitally disordered orthorhombic phase, and R to a rhomboidal phase. PI and PM are, respectively, paramagnetic-insulator and paramagnetic-metal phases. After Goodenough, J.B., Zhou, J.-S., 2001. Structure and Bonding 98, 87.

extension of the parallel spin-density domain increases as the concentration of itinerant electrons decreases and their effective mass increases.

Additional Illustrative Examples

Spinel

The dominant interaction in the ferromagnetic spinel $\text{Fe}[\text{NiFe}]\text{O}_4$ is the antiferromagnetic $135^\circ t^3 - \text{O} - e^2$ interaction between half-filled σ -bonding orbitals on the tetrahedral-site $\text{Fe(III)}: e^2 t^3$ and the octahedral-site $\text{Ni(II)}: t^6 e^2$ and $\text{Fe(III)}: t^3 e^2$ ions.

In an $\text{A}[\text{M}_2]\text{O}_4$ spinel in which the tetrahedral-site A cation has no spin, the only spin-spin interactions are those between octahedral-site transition-metal atoms M. The octahedral-site cations in the spinel structure of Figure 4 share only octahedral-site edges; they interact with one another by M-M and $90^\circ \text{M}-\text{X}-\text{M}$ interactions. The octahedral-site $\text{Cr(III)}: t^3 e^0$ cations in $\text{Zn}[\text{Cr}_2]\text{O}_4$, $\text{Zn}[\text{Cr}_2]\text{S}_4$, and $\text{Cd}[\text{Cr}_2]\text{S}_4$ all have ferromagnetic $90^\circ \text{Cr}-\text{X}-\text{Cr}$ interactions by direct exchange and $t^3 - p_{\pi\sigma} - e^0$ superexchange whereas the $t^3 - t^3$ interactions are antiferromagnetic by superexchange. The antiferromagnetic $t^3 - t^3$ interactions decrease exponentially with increasing Cr-Cr separation, that is, with increasing lattice parameter on going from $\text{Zn}[\text{Cr}_2]\text{O}_4$ to $\text{Zn}[\text{Cr}_2]\text{S}_4$ to $\text{Cd}[\text{Cr}_2]\text{S}_4$. The $90^\circ \text{Cr}-\text{X}-\text{Cr}$ interactions, on the other hand, increase significantly on going from an oxide to a more covalent sulfide. Experimentally, $\text{Cd}[\text{Cr}_2]\text{S}_4$ is a ferromagnetic insulator, the Cr-Cr interactions in $\text{Zn}[\text{Cr}_2]\text{S}_4$ are just strong enough to convert the ferromagnetic coupling into an SDW, and in $\text{Zn}[\text{Cr}_2]\text{O}_4$ stronger antiferromagnetic Cr-Cr interactions are frustrated to give a low T_N .

As pointed out above, Fe_3O_4 is a good electronic conductor because of mixed Fe(III) and Fe(II) valence states on the octahedral sites. On the other hand, Mn_3O_4 and Co_3O_4 are insulators because the Mn(II) and Co(II) ions occupy tetrahedral sites having a different potential energy for the $\text{M(II)}/\text{M(III)}$ couple than that at the octahedral sites. With $\text{Mn(III)}: t^3 e^1$ on octahedral sites, Mn_3O_4 undergoes a cooperative Jahn-Teller orbital ordering that distorts the spinel from cubic to tetragonal symmetry; the room temperature axial ratio is $c/a = 1.16$. Fe_3O_4 is a Néel ferrimagnet with ferromagnetic double-exchange coupling among the octahedral sites whereas antiferromagnetic $t^3 - t^3$ interactions between octahedral-site Mn(III) lead to a complex magnetic order. Co_3O_4 is a Néel antiferromagnet because the octahedral-site $\text{Co(III)}: t^6 e^0$ ions are in their low-spin state with $S = 0$ and the tetrahedral sites consist of two interpenetrating face-centered-cubic arrays as in the diamond structure with antiferromagnetic $t^3 - \text{O} - t^3$ superexchange interactions between the $\text{Co(II)}: e^4 t^3$ ions.

Rutile

Most MX_2 compounds with $\text{X} = \text{F}$ or O crystallize in the rutile structure of Figure 9. This structure has a body-centered-tetragonal array of octahedral-site cations that share edges along the c -axis; these c -axis chains share octahedral-site corners. The anions form $sp^2\sigma$ -bonds with three cation neighbors and π -bond with two quasidegenerate t orbitals, e_π ; the other t orbital, $d_{||}$, is directed along the c -axis where it overlaps with the corresponding $d_{||}$ orbitals of two next-near-neighbor cations. The MO_2 oxides illustrate several features discussed above.

Figure 9 The tetragonal rutile structure and the cation displacements (arrows) found in VO_2 at $T < 67^\circ \text{C}$.

The bottom of the empty $3d$ bands of TiO_2 lies ~ 3 eV above the top of the filled $\text{O}-2p$ bands, which makes TiO_2 an insulator and a crystal transparent. However, the Ti(IV) are not displaced from the center of their octahedra as in BaTiO_3 and PbTiO_3 which are ferroelectrics. In TiO_2 , there is no spontaneous displacement, but displacements in an electric field give TiO_2 a large dielectric constant, which makes TiO_2 a white pigment widely used in paint and the finishing of paper. The itinerant-electron $3d$ bands can be doped n -type, in which case $n\text{-TiO}_2$ can be used for photoelectrolysis. Removal of oxygen is accommodated by an ordering of the oxygen vacancies into ‘shear planes’ that separate slabs, n rutile cells wide, in a $\text{Ti}_n\text{O}_{2n-1}$ family of shear structures. Ti(IV) octahedra share common faces across a shear plane, and electrostatic forces displace the cations toward opposite site faces; itinerant electrons reside on the Ti cations within the rutile slabs. The formation of shear planes allows cooperative displacements of the Ti(IV) cations, which reduces the cost in elastic energy. The shear-plane phenomena are associated with cations that also exhibit ferroelectric displacements in other contexts. At low temperatures, the itinerant electrons within the $3d$ bands of a slab condense into $d_{\parallel}-d_{\parallel}$ homopolar bonds to form pairs of Ti(III) displaced toward one another. In Ti_4O_7 , these two-electron bonds are mobile and disordered in a small temperature interval above the long-range ordering temperature $T_1 \approx 160$ K. The mobile electron pairs represent bipolarons.

Above 67°C , the single $3d$ electron of a V(IV) cation occupies overlapping itinerant-electron bands of $d_{\parallel}$ and e_{π} parentage; the metallic conductivity is nearly isotropic. The $d_{\parallel}$ band is formed by strong $\text{V}-\text{V}$ interactions along the c -axis: the π^* bands by strong $e_{\pi}-\text{O}:2p_{\pi}-e_{\pi}$ interactions with nearest and next-nearest neighbors. Below 67°C , these itinerant electrons condense into $d_{\parallel}-d_{\parallel}$ homopolar bonds and the smaller V(IV) cations are also displaced toward a corner-sharing oxygen by a rocking of the pairs to form molecular clusters consisting of two vanadyl $(\text{V}=\text{O})^{2+}$ cations bonded by a homopolar $\text{V}-\text{V}$ bond. The oxygen atoms that bridge a $\text{V}-\text{V}$ bond each belong to another such cluster. The resulting monoclinic-tetragonal first-order transition at $T_1 = 67^\circ\text{C}$ produces an insulator-metal transition across which the formation of the $\text{V}=\text{O}$ vanadyls lifts the π^* bands above the Fermi energy, leaving the $d_{\parallel}$ band half-filled, and $\text{V}-\text{V}$ pairing introduces a gap in the narrow $d_{\parallel}$ band that localizes the electrons in homopolar bonds. This localization of electrons to a molecular cluster is to be distinguished from formation of a 1D CDW as envisioned by a ‘Peierls distortion’ in which the electrons of the pairs remain itinerant.

In CrO_2 , the $\text{Cr}-\text{Cr}$ separation along a c -axis chain is too large ($R > R_c$) for the $d_{\parallel}$ electrons to form a band of itinerant-electron states; they form localized $d_{\parallel}^1$ states separated from a $d_{\parallel}^2$ configuration by a finite energy gap ($U - W_{\parallel}$). The remaining single e_{π} electron occupies a π^* band of itinerant-electron states. This band is one-quarter filled, and extrapolation of the superexchange rules to band magnetism would predict ferromagnetic correlations among the e_{π} electrons; and CrO_2 is a ferromagnetic metal. Below the Curie temperature T_c , the c -axis expands as a result of ‘exchange striction’; the half-filled $d_{\parallel}^1$ orbitals would be stabilized by antiferromagnetic superexchange, but their parallel alignment removes the c -axis bonding by the $d_{\parallel}$ electrons because the Pauli exclusion principle prevents $d_{\parallel}$ -electron transfer if the spins are parallel.

In MnO_2 , both the $d_{\parallel}$ and the e_{π} electrons are localized and a $d_{\parallel}^1 e_{\pi}^2$ manifold means that both sets of orbitals are half-filled, which leads to antiferromagnetic interactions between nearest and next-nearest neighbors by superexchange. Since both nearest and next-nearest neighbors share a common $\text{O}-2p_{\pi}$ orbital, the antiferromagnetic interactions along the c -axis are stronger than those between nearest neighbors, and the competition leads to the antiferromagnetic spiral-spin configuration propagating along the c -axis that is illustrated in Figure 5.

The $4d$ electrons have a greater radial extension than the $3d$ electrons, so they have larger overlap integrals with neighboring atoms than do the $3d$ orbitals. Consequently, NbO_2 and MoO_2 do not have localized $4d$ electrons; they both form c -axis $\text{M}-\text{M}$ pairs, but without the rocking of the pairs that occurs in VO_2 . The homopolar-bond states of NbO_2 lie below the bottom of the π^* band of e_{π} -orbital parentage, and NbO_2 is a semiconductor below $T_1 \approx 800^\circ\text{C}$. With one additional $4d$ electron, MoO_2 has one electron per formula unit in the π^* bands and is a metal. Low-spin Ru(IV) and Rh(IV) are also accessible in octahedral sites of an oxide, but they contain too many $4d$ electrons to allow stabilization of homopolar bonds in $\text{M}-\text{M}$ pairs. With two and one hole per formula unit, respectively, in the $d_{\parallel}$ and π^* bands, these oxides are metallic and retain the rutile structure to lowest temperatures.

Energy Bands and Redox Couples

Electron Energies

In an ionic model of a compound, which is illustrated in Figure 10 for MnO , the energy E_1 required to remove the last electron from the cation and place it on an O^- ion at infinite separation is more than compensated by the electrostatic Madelung energy $E_M > E_1$ that is gained by assembling the point charges in a crystalline array. Conservation of energy raises the cation energy levels and lowers the anion energies. The crystalline electric field at the octahedral-site Mn^{2+} of MnO raises the $\text{Mn}:3d^5$ level into the energy gap $E_g \approx 6$ eV between the filled $\text{O}^{2-}:2p^6$ and empty $\text{Mn}^{2+}:4s^0$ bands. Covalent back transfer of electrons from the O^{2-} to the Mn^{2+} ions reduces E_M , but it introduces a compensating quantum-mechanical repulsion between the bonding $\text{O}-2p$ and antibonding $\text{Mn}-4s$ orbitals to retain a large E_g . The covalent mixing and the like-atom interactions broaden the bonding and antibonding s and p states into bands of one-electron itinerant-electron states, and it is convenient to label the upper bonding bands as $\text{O}^{2-}:2p^6$ bands and the lower antibonding bands as $\text{Mn}:4s^0$.

Where a d^n or $4f^n$ manifold falls in the energy gap E_g , as occurs in MnO , further oxidation of the cation is possible. Similarly, where an empty d^{n+1} manifold lies in the gap, reduction of the cation is possible if this manifold is not too close in energy to the bottom of the broad s and p antibonding bands. In the case of octahedral-site manganese, three valence states are stable: Mn(II) , Mn(III) , and Mn(IV) corresponding to $\text{Mn(III)}/\text{Mn(II)}$ and $\text{Mn(IV)}/\text{Mn(III)}$ redox couples lying in the gap. The splitting $U_{\text{eff}} - U_{\sigma}$

Figure 10 Schematic construction of electronic energies from the point-charge model, (a) and (b), to energy bands for Mn:4s⁰ and O²⁻:2p⁶ in (c) and (d).

between the Mn(II): t^3e^2 and Mn(III): t^3e^1 energies is small; in fact, W_σ approaches U_σ in the perovskites LaMnO₃ and SrMnO₃ containing Mn(III) and Mn(IV), respectively, and a $\tau_h < \omega_R^{-1}$ for the σ^* electrons makes La_{0.7}Sr_{0.3}MnO₃ a ferromagnetic metal.

Since $E_M - E_1$ decreases on going from the halides (group VII) to the oxides and chalcogenides (group VI) to the pnictides (group V) and down any column of the periodic table to heavier anions, the energy gap E_g between bonding and antibonding s and p bands decreases accordingly. Consequently, the higher cation valence states accessible in an oxide may not be available in a sulfide or selenide. For example, the Mn²⁺: d^5 manifold lies below the S²⁻: $3p^6$ energy in the point-charge model, so the Mn(IV) state is not accessible in the chalcogenides. MnS₂ is Mn²⁺(S₂)²⁻, for example, in contrast to Mn⁴⁺(O²⁻)₂ in MnO₂. However, where a d^n manifold lies close to the top of the bonding anion- p bands, covalent mixing raises antibonding states of d -orbital symmetry to the top of the broad bonding bands; the redox couple becomes pinned at the top of the bonding bands and changes from primarily d to primarily anion- p character as the d^n manifold falls below the anion- p^6 energy in the point-charge model. Where the anion component becomes dominant, the electronic states of the redox couple are itinerant; and where both the hole concentration and the anion character in these itinerant antibonding states are large enough for a cooperative condensation of the holes into purely anion antibonding states of anion-anion pairs, diatom anions are formed.

Rare-Earth Compounds

An energy $U > E_g \gg W$ separates the $4f^n$ and $4f^{n+1}$ localized-electron manifolds of the rare-earth ions. Therefore, they have a single R³⁺ valence state unless a $4f^n$ configuration falls within E_g , as occurs for the Ce³⁺: $4f^1$ and Pr³⁺: $4f^2$ or the Eu²⁺: $4f^7$ in an oxide. However, the R-5d orbitals are itinerant, and covalent bonding pushes the antibonding 6s and 6p states above the bottom of the 5d band. Normally the 5d band is empty, but it can accept electrons. Doping EuO with Gd substitution for Eu, for example, creates shallow one-electron donor states below the bottom of the 5d conduction band just as substitution of P for Si creates n -type silicon. In EuO, the Eu:4f⁷ level lies ~ 1.1 eV below the bottom of the 5d band; the 4f⁷-O-5d⁰ superexchange interactions are ferromagnetic and stronger than the antiferromagnetic 4f⁷-O-4f⁷ interaction because of the large U_{eff} between 4f⁷ and 4f⁸ as well as the smaller overlap integrals. In the Eu_{1-x}Gd_xO system, the YKKY indirect exchange by itinerant 5d electrons initially increases the ferromagnetic Curie temperature T_c with x ; but as x increases, the extension of the ferromagnetic 5d volume about a rare-earth atom decreases to below a nearest-neighbor separation; the YKKY interaction becomes antiferromagnetic, and T_c decreases with a further increase of x . Eu_{1- δ} O contains polaronic $\tau_h > \omega_R^{-1}$ holes in the Eu(III)/Eu(II) redox couple. On the other hand, annealing in a Eu atmosphere creates EuO_{1- δ} , and the oxygen vacancies trap two electrons. On cooling EuO_{1- δ} below the Curie temperature T_c , the 5d electrons with spin parallel to the 4f⁷ spin $S=7/2$ are stabilized relative to the 5d electrons of antiparallel spin by direct intra-atomic exchange. The spin degeneracy of the two-electron trap state is also removed, the energy of the antiparallel trapped electron is raised above the bottom of the parallel-spin 5d conduction band. As a result, EuO_{1- δ} transforms from a semiconductor to a metal on cooling through T_c as is illustrated in Figure 11. Just above T_c , the carriers thermally excited into the 5d band stabilize regions of short-range ferromagnetic order by double-exchange electron transfer; ferromagnetic alignment reduces the spin-disorder scattering of the mobile electrons, and their stabilization by the intra-atomic exchange interaction confines the mobile electrons to the region of short-range ferromagnetic order. A mobile electron confined to clusters of short-range ferromagnetic order is called a 'magnetic polaron.' In an external magnetic field, the size of the ferromagnetic clusters grows; at a percolation threshold, the compound undergoes a drop in electrical resistance. This magnetoresistance is large in EuO.

The valence state of a rare-earth ion is defined by its occupied $4f^n$ configuration. Eu_{1- δ} O is in a mixed Eu³⁺/Eu²⁺ valence state since the holes occupy the Eu³⁺/Eu²⁺ 4f⁶/4f⁷ couple. GdS, on the other hand, has the Gd configuration 4f⁷5d¹, and the itinerant 5d electrons that make GdS a metal are valence electrons. Therefore, the Gd of GdS is considered to be in the trivalent state corresponding to a localized 4f⁷ configuration. SmS has its 4f⁶ level just below the bottom of the 5d band; pressure increases the width of the 5d band, and above 6.5 kbar the 5d band overlaps the 4f⁷ level. A first-order contraction of the rocksalt structure at

Figure 11 Resistivity vs. temperature for EuO annealed in a europium-rich atmosphere ($\text{EuO}_{1-\delta}$) and an oxygen-rich atmosphere ($\text{Eu}_{1-\delta}\text{O}$). After Oliver, M.R., Dimmock, J.O., McWhorter, A.L., Reed, T.B., 1972. *Physical Review B* 5, 1078.

crossover raises the $4f^6$ level into the $5d$ band to where 0.5 electrons per Sm are donated to the $5d$ band. Hybridization of $5d$ and $4f$ states creates 'heavy fermions' at the Fermi energy and the compound is said to be in an intermediate-valence state.

Transition-Metal d -Block Compounds

The smaller U_{eff} of the d -block transition-metal compounds makes localized $4d$ and $5d$ spins relatively rare; localized spins associated with $3d$ electrons are common, but they may also be itinerant as discussed above for oxides with a rutile structure. The existence of four valence states for vanadium in V_2O_5 , VO_2 , V_2O_3 , and VO shows that the $U_{\text{eff}} = U_{\pi}$ separating octahedral-site t^1 , t^2 , and t^3 configurations is in the neighborhood of 2 eV, which makes $W \approx U_{\text{eff}}$ in these compounds. Both VO_2 and V_2O_3 exhibit insulator-metal transitions due to cation clustering. V_2O_5 contains short $\text{V}=\text{O}$ bonds due to displacement of the V(V) from the center of symmetry of its interstice, and VO is a semimetal exhibiting V-V bond-length fluctuations. On the other hand, the Ti-Ti interactions in metallic TiO make $W > U_{\pi}$; it becomes a conventional superconductor below $T_{\text{cs}} = 1$ K.

For a given valence state, the effective nuclear charge seen by the d electrons increases on going to heavier atoms of a given d -block and the redox energy is correspondingly stabilized. However, in an octahedral site, the splitting U_{eff} between a $\text{Cr(III)}: t^3e^0$ and a $\text{Cr(II)}: t^3e^1$ configuration is increased by the cubic-field splitting Δ_c , which is why CrO has not been prepared; the $\text{Cr(III)}/\text{Cr(II)}$ level lies close to the bottom of the $4s$ band. However, CrS has been prepared; it has hexagonal rather than cubic close-packing of the anions (NiAs rather than NaCl structure) with a cooperative Jahn-Teller orbital ordering that distorts the structure from hexagonal symmetry. The d^5 configuration of MnO is more stable than the d^6 configuration of $\text{Fe}_{1-\delta}\text{O}$ because a $U_{\text{eff}} = U_{\pi} + \Delta_{\text{ex}}$ separates the $\text{Fe(III)}: t^3e^2$ and $\text{Fe(II)}: t^4e^2$ octahedral-site states. Since the majority-spin electrons occupy different d orbitals, they are more tightly bound to the nucleus than the minority-spin electron, which is why the minority-spin electron of Fe_3O_4 can have a $\tau_{\text{h}} \approx \omega_{\text{R}}^{-1}$.

The antiferromagnetic order in MnO is illustrated in **Figure 12**. The dominant interactions are 180° Mn(II)-O-Mn(II) antiferromagnetic superexchange interactions between half-filled t^3 and e^2 configurations; these interactions order parallel the spins of a $(1\ 1\ 1)$ plane, whereas the t^3-t^3 superexchange interactions across shared octahedral-site edges within these planes are antiferromagnetic. Parallel spin alignment makes these t^3-t^3 interactions nonbonding, whereas those between neighboring, antiparallel $(1\ 1\ 1)$ planes are bonding. Consequently, MnO distorts from cubic to rhombohedral ($\alpha > 60^\circ$) symmetry on cooling through T_{N} as a result of exchange striction. Similar antiferromagnetic $180^\circ e^2-\text{O}-e^2$ superexchange interactions are dominant in $\text{Fe}_{1-\delta}\text{O}$ and CoO , but these compounds exhibit a distortion below T_{N} that is due to a large magnetostriction; the orbital degeneracies

Figure 12 Spin configurations of antiferromagnetic MnO. After Shull, C.G., Strauser, W.A., Wollan, E.O., 1951. *Physical Review* 83, 333.

of the $\text{Fe(II)}:t^4e^2$ and $\text{Co(II)}:t^5e^2$ configurations are removed by an enhancement of the orbital angular momentum once long-range collinear ordering of the spins allows ordering of the orbital angular momentum through the spin-orbit coupling $\lambda\mathbf{L}\cdot\mathbf{S}$. $\text{Fe}_{1-\delta}\text{O}$ becomes rhombohedral ($\alpha < 60^\circ$) below T_N with spins oriented parallel to the $[1\ 1\ 1]$ axis in opposition to the dipole-dipole forces; CoO becomes tetragonal ($c/a < 1$) and the dipole-dipole interactions force the spins a little away from the tetragonal c -axis.

Pinning of a redox couple at the top of an anion- p band replaces the gap U_{eff} with a charge-transfer gap $\Delta = \Delta E_p$. The $\text{Ni(II)}:t^6e^2$ configuration of NiO is pinned at the top of the $\text{O-}2p$ bands, and a $\Delta < U_{\text{eff}} = U_\sigma + \Delta_{\text{ex}}$ adds a semicovalent exchange comparable to the superexchange antiferromagnetic $\text{Ni(II)}:e^2 - \text{O} - \text{Ni(II)}:e^2$ interaction provide a high Néel temperature. In NiS , the $\text{Ni(I)}:t^6e^3$ configuration is at the top of the $\text{S-}3p$ bands. At temperatures $T > 350^\circ\text{C}$, NiS has the NiAs structure, but it transforms into the peculiar millerite structure at lower temperatures. It is possible to retain the NiAs structure at low temperatures by quenching from above 650°C . This metastable phase undergoes a first-order insulator-metal transition at a Néel temperature $T_N = 264\text{ K}$. On lowering the temperature through T_N , there is an abrupt increase in volume with only a small distortion of the structure as the width of the σ^* band of e -orbital parentage changes from $W_\sigma \approx U_{\text{eff}} = U_G + \Delta_{\text{ex}}$ to $W_\sigma < U_{\text{eff}}$; the Mott-Hubbard transition is not smooth.

The lattice instabilities occurring where $W \approx U_{\text{eff}}$ are more commonly expressed by either stabilization of a CDW or, in a mixed-valent compound, by a dynamic spinodal phase separation. For example, the low-spin $\text{Ni(III)}:t^6e^1$ configuration in the RNiO_3 family of **Figure 13** is pinned at the top of the $\text{O-}2p$ bands; this single-valent family undergoes a transition from an antiferromagnetic insulator with $W < U_\sigma$ to metallic LaNiO_3 with $W > U_\sigma$ as the $(180^\circ - \phi)$ Ni-O-Ni bond angle increases with increasing size of the rare-earth R^{3+} ion. The samples in the shaded area of **Figure 13** exhibit bond-length fluctuations and stabilization of a CDW below a $T_i = T_N$ that are characteristic of the lattice instabilities encountered at crossover. Below the insulator-metal transition T_{MI} , a distortion to monoclinic $\text{P}2_1/n$ symmetry reflects bond-length fluctuations that become static for $\text{R} = \text{Ho}, \dots, \text{Lu}, \text{Y}$ with long-range ordering of Ni(III) ions distinguished by alternating covalent and ionic Ni-O bond lengths. Moreover, applying pressure to PrNiO_3 lowers $T_{\text{MI}} = T_N$ until it terminates at a first-order transition to a quantum-critical-point phase.

Pinning of a redox couple at the top of the $\text{O-}2p$ bands may also be revealed by oxidation of the transition-metal array. For example, the $x=0$ composition of the layered $\text{Li}_{1-x}\text{CoO}_2$ cathode material contains low-spin $\text{Co(III)}:t^6e^0$ and is a charge-transfer-gap semiconductor. However, the t^5/t^4 $\text{Co(IV)}/\text{Co(III)}$ redox couple is pinned at the top of the $\text{O-}2p$ bands, and removal of Li from between adjacent CoO_2 layers of edge-shared octahedra creates a two-phase region $0.1 < x < 0.4$ in which a semiconductive phase and a metallic phase of smaller Co-Co separation coexist as a result of a strong intra-atomic Δ_{ex} in isolated high-spin $\text{Co(IV)}:t^3e^2$. At $x > 0.6$, peroxide formation at the surface leads to the loss of oxygen as gaseous O_2 .

The high-temperature copper-oxide superconductors provide an example where strong electron-lattice interactions in a mixed-valent system at the $\tau_h \approx \omega_R^{-1}$ crossover leads to a remarkable physical phenomenon. In these layered oxides, the $x^2 - y^2$ orbital of the $\text{Cu(III)}/\text{Cu(II)}$ couple is pinned at the top of the $\text{O-}2p$ bands of a CuO_2 sheet. The $(\text{CuO}_2)^{2-}$ planes of the single-valent parent compounds are antiferromagnetic insulators, but removal of electrons from these sheets induces a transition from the antiferromagnetic phase to a metallic phase that is not superconductive. Superconductivity appears in an intermediate $\tau_h \approx \omega_R^{-1}$ crossover phase where there is a strong electron coupling to bond-length fluctuations that order into a traveling CDW (or stripes) phase at low temperatures as is illustrated in **Figure 14** for the $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ system.

Figure 13 Schematic phase diagram of the RNiO_3 (R = rare-earth) family. The triangle symbol is for the $^{18}\text{O}/^{16}\text{O}$ isotope effect, the diamond is for the lattice contribution to the thermal conductivity at 100 K; both of these signal bond-length fluctuations in the shaded region. In the nonshaded region, a $T_N \sim \langle \cos^2 \phi \rangle$ indicates localized-electron antiferromagnetism; LaNiO_3 is metallic. Introduction

The successful extension of semiconductor technology to fabricate mechanical parts of the sizes from 10–100 μm opened wide ranges of possibilities for micromechanical devices and systems. The fabrication technique is called micromachining. Micromachining processes are based on silicon integrated circuits (IC) technology and used to build three-dimensional (3D) structures and movable parts by the combination of lithography, etching, film deposition, and wafer bonding. The same technology base that enabled miniaturization and large-scale integration of electronics offers three distinctive features defining micromachined devices and systems: miniaturization, multiplicity, and microsystem integration. Miniaturization is clearly essential. Small parts respond fast, constitute miniature machines that work in extremely shallow spaces, add functionality to portable or wearable devices, and realize tools to investigate the nanometric world. Millions of such parts can work cooperatively to do things impossible for a single device alone. Thus, multiplicity is one key to successful micromechanical systems. The coordination of these parts is accomplished by integrating them with electrical circuits. Furthermore, optical, sensing, fluidic, and biological elements are to be integrated in multi-functional microsystems in a cost-effective manner. The research field concerning micro-mechanical devices is referred to as MEMS (microelectromechanical systems) in USA, Micromachine in Japan, and MST (micro-system technology) in Europe.

The root of MEMS research can be found in the research of silicon sensors. A noticeable turning point from sensor research toward MEMS research was the demonstration of micromachined gears and turbines made on a silicon chip in 1987. Since then, development has continued in micromachining processes, material varieties, microactuators, and the application of MEMS.

Micromachining

MEMS generally requires complex microstructures that are thick, 3D, and movable. Therefore, many technologies have been developed on the basis of semiconductor microfabrication processes including lithography, etching, and deposition. Pre-designed patterns are transferred by exposure to resists that have sensitivity to light, X-ray, or electron beam and those that are coated on substrates. Photo-lithograph through a glass-chromium mask is most commonly used. Parts of the resist remain on the substrate according to the exposed patterns by development. Using the resist pattern as a masking layer, one can selectively etch the substrate or the film on it. In another process, the resist mold pattern can be replicated by deposition. After resist removal, the next material is deposited on the patterned substrate. The material is, then, patterned by lithography and etching. These sequences are very similar to the IC fabrication.

There are special processes for micromachining to obtain 3D structures and movable parts (**Table 1**). To construct 3D microstructures, researchers have used anisotropic wet etching, deep reactive ion etching, and replication of deep lithography patterns. Another 3D fabrication technique is capable of folding micromachined plates out from the substrate by removing either a thin film under it or the substrate itself. The removal process is called sacrificial layer etching. Selective etching of the ‘sacrificial’ material should be performed without damaging microstructures. **Table 2** shows the choice of etching solution or gas, the structural material and the sacrificial material. Even after release etching, microstructures tend to stick to the substrate. Sublimation drying,

[☆]*Change History:* July 2015. S. Elsheikhi added abstract and keywords, expanded text with additional review materials, updated the list of reference, and provided an Change History.

Table 1 Micromachining processes

<i>Process (material)</i>	<i>Feature</i>	<i>Application</i>
Wet anisotropic etching (single-crystal silicon)	Precise structures defined by crystal facets	Pressure sensor membrane, V-groove (channel, fiber alignment), Optical flat mirror surface
Dry anisotropic etching (silicon)	3D structure defined by mask patterns	High aspect ratio microstructure, through hole
Sacrificial layer etching (various thin films)	Integrated circuits compatible fabrication of micromovable structures	Integrated sensor, Arrayed MEMS (e.g., digital micromirror device)
Wafer bonding (Si or glass substrate)	Closed cavity formation, 3D assembly of devices on substrates	Hybrid integration of multifunctional system, Packaging, and encapsulation
Electroforming (metal)	Replication of resist patterns by electroplating through the resist mask	Metallic 3D structures, Mater for injection molding
Injection molding and thermal embossing (polymer)	Low cost replication from precise master	3D microstrutures for fiber alignment or microchannels

Table 2 Selectivity of etching

<i>Etching liquid/gas</i>	<i>Etched material</i>	<i>Resistant material</i>
HF(+NH ₄ F)	SiO ₂	Si
KOH	Si	SiO ₂ , Si ₃ N ₄
Hot H ₃ PO ₄	Si ₃ N ₄	SiO ₂ , Si
XeF ₂ (gas)	Si	SiO ₂ , Si ₃ N ₄
SF ₆ (plasma)	Si	Ni, Al
O ₂ (plasma)	Polymer	Al

supercritical drying, release etching by plasma or gas, and surface coating are typical methods to prevent sticking. Wafer bonding is also essential to micromachining. 3D stacking of structures, sealing of cavities and channels, hermetic or vacuum encapsulation of sensing/actuation elements and combination of devices made of different materials and processes are accomplished by bonding wafers together. Glass and silicon substrates are bonded by applying 400–500 V at 600–800 K; this is called anodic bonding. Two silicon substrates can be fusion bonded at ~1370 K after careful cleaning of the surfaces to CO₂ bonded. Replication of micro molds is the inexpensive way of fabricating many microstructures. Molds can be made by deep lithography or deep etching. Electroplating of metals, chemical vapor deposition (CVD) of polysilicon films, and injection molding of polymers are commonly used for replication. Finally, direct fabrication of microstructures may be possible by beam assisted deposition or solidification by laser beam, electron beam assisted deposition, and focused ion beam (FIB) etching.

In recent years some multifunctional machine tools have been developed to implement several mechanical machining operations on one machine in order to rapidly and economically fabricate those components/products. Research has also focused on the development of hybrid machines that can integrate conventional and non-conventional machining processes in a single platform. Hybrid micro-machining processes have been significantly improved in terms of machinability of hard-to-machine materials, tool life, geometrical accuracy, surface integrity and machining efficiency (Chavoshi and Luo, 2015). In 2014, the College International Pour la Recherche en Productique (CIRP) collaborative working group on hybrid processes proposed the following definition for 'hybrid machining processes': *hybrid machining processes are based on the simultaneous and controlled interaction of machining mechanisms and/or energy sources/tools having a significant effect on the process performance*. The wording 'simultaneous and controlled interaction' means that the processes/energy sources should interact more or less in the same processing zone and at the same time (Lauwers *et al.*, 2014). Accordingly, these hybrid micro-machining processes are classified as *assisted* (vibration-assisted, laser-assisted, fluid-assisted, magnetic field-assisted and external electric field-assisted) and combined hybrid micromachining processes (ECDM: micro-electrochemical discharge machining, SEDCM: simultaneous micro-EDM and micro-ECM, JECM-LD: Laser drilling assisted with jet electrochemical machining, ECM-Grinding: electrochemical machining for grinding and EDM-ER: Micro-electrodischarge machining and electrorheological fluid-assisted polishing) (Chavoshi and Luo, 2015).

Materials for MEMS

Silicon is the most common material in micromachining because (1) the fabrication processes are well established, (2) it has excellent mechanical properties, and (3) integration with electronic circuits and sensors is possible. It also has piezoresistive properties used for strain detection. SiO₂ and SiN films serve as electrical and thermal insulators. They are also excellent masking layers for anisotropic wet etching by TMAH and KOH. Optical waveguides may be made of SiO₂. SiN and other nitride films, for example, TiN and AlN, are very hard and used for low friction and antiwear coating.

Other materials that may not be common for IC fabrication are also useful in MEMS. Actuator materials produce force and displacement. They include piezoelectric materials (PZT, ZnO, quartz), magnetostrictive material (TbFe), shape memory alloy

(TiNi), and some conductive polymers. Compound semiconductors such as GaAs, GaN, and InGaAs can be micromachined in a way similar to silicon, and offer optically active and passive components. MEMS devices can be made from polymers by processes such as injection moulding, embossing or stereolithography and are especially well suited to microfluidic applications such as disposable blood testing cartridges (Mamilla and Chakradhar, 2014).

Metals can also be used to create MEMS elements. While metals do not have some of the advantages displayed by silicon in terms of mechanical properties, when used within their limitations, metals can exhibit excellent reliability. Metals can be deposited by electroplating, evaporation, and sputtering processes. Commonly used metals include gold, nickel, aluminum, copper, chromium, titanium, tungsten, platinum, and silver (Mamilla and Chakradhar, 2014).

Researchers have developed batch fabrication processes for all of those materials achieving the features of MEMS mentioned above.

Microactuators

Microactuators are key devices allowing MEMS to perform physical functions. Many types of microactuators have been successfully operated. Some of them are driven by force associated with physical fields. Force can be generated in the space between stationary and moving parts using electric, magnetic, and flow fields. Some others utilize actuator materials introduced before. Thermal expansion and phase transformations, such as the shape-memory effect and bubble formation, cause shape or volume changes. Micromachining technology allows one to make structures in which a well-controlled field is generated or to deposit and pattern actuator materials. Typical sizes of microactuators are from 10 μm to 1 mm. Although the physical principle that describes the motion of macroscopic objects is still applicable to microactuators, the relative importance of various forces changes in small dimensions. It is called a scaling effect. Table 3 shows the dependence of some physical parameters and forces on the characteristic dimension of an object. The scaling effect and the compatibility with micromachining process are important issues when a microactuator is designed.

One of the most significant scaling effects is that friction dominates over inertia forces in the micro world. Researchers have tried many ways of minimizing friction by suspending movable parts with flexures, applying smooth coatings, using rotational contacts, levitating objects, and using friction drive mechanism.

Each actuation principle has its own advantages and disadvantages (Table 4). The choice and optimization of an approach should be made according to the requirements of a particular application. Generally speaking, the electrostatic actuator is more suitable for performing tasks that can be completed within a chip (e.g., positioning of devices/heads/probes, sensors with servo feedback for self-test or readout, light deflection and modulation) since it is easily integrated on a chip, easily controlled, and consumes little power. On the contrary, the other types of actuators are more robust, more capable of producing larger forces, and more suitable for performing external tasks (propulsion, manipulation of objects, etc.).

Table 3 Scaling effect (L : characteristic dimension)

Parameter	Formula	Scaling	Comment
Gravity, f_g	Mg	L^3	g : gravity const., m : mass
Inertial force, f_i	Ma	L^4	a : acceleration
Elasticity, f_e	$eS\Delta L/L$	L^2	e : Yang's modulus
Surface tension, F_s	$L\gamma$	L	γ : surface wetting constant
Resonant frequency, ω	$\sqrt{K/m}$	L^{-1}	M : spring constant ($\propto L$)
Moment of inertia, I	$\alpha m r^2$	L^5	α : shape constant, r : radius of rotor
Reinors number, R_e	f/f_r	L^2	Ratio between inertia and viscosity ($\propto L^2$)
Heat conduction, Q_c	$\lambda \delta TA/d$	L	δT : temperature difference, λ : heat conductivity, A : cross-section area ($\propto L^2$)
Thermal expansion, F_T	$eS\Delta L(T)/L$	L^2	Valid for piezoelectric deformation ($\Delta L(E)$)
Magnetic force, F_m	$\mu SH^2/2$	L^4	μ : permittivity, H : magnetic field ($\propto L$)
Electrostatic force, F_e	$\epsilon SE^2/2$	L^2	ϵ : permittivity, E : electric field (constant)

Table 4 Comparison of driving principles

	Electrostatic	Magnetic	Piezoelectric	Shape memory alloy	Thermal
Speed	Excellent	Good	Good	Fair	Poor
Force	Poor	Good	Excellent	Excellent	Excellent
Integration with circuits	Excellent	Good	Fair	Good	Excellent
Power consumption	Excellent	Fair	Good	Fair	Poor
Robustness in harsh environments	Poor	Good	Good	Excellent	Excellent

Applications

Figure 1 maps the prospective applications in optics, transportation and aerospace, robotics, chemical analysis systems, bio-technologies, medical engineering, and microscopy using scanning microprobes. Most of these applications have a common feature in that only very lightweight objects such as mirrors, heads, valves, cells, and microprobes are driven, and very little physical interaction with the external environment is necessary.

Sensors

The first successful application of MEMS was pressure sensors for the precise control of an automobile engine combustion for clean exhaust in 1980s. MEMS accelerometers are currently used for air bag ignition sensors. MEMS gyroscopes, or angular rate sensors, are applied to navigation systems, active suspensions, and spin suppression systems. Precisely micromachined membranes serve as pressure sensing element; its deflection by applied pressure is detected by piezoresistive gauges made on the silicon membrane. In the accelerometer, a proof mass suspended by a flexible suspension is micromachined (**Figure 2**). When acceleration is applied to the proof mass, the initial force displaces the mass and the suspension; this motion is detected by either the strain gage, that is, an integrated piezoresistor, or the change in capacitance between the mass and a fixed electrode. Better linearity and stability can be

Figure 1 A map of MEMS applications.

Figure 2 Micromachined accelerometer.

achieved by feedback measurement in which the inertia force is canceled by electrostatic force; the magnitude of the force is proportional to the acceleration.

Another application of MEMS sensors relates to the tracking of rehabilitation progress of stroke patients by monitoring parameters such as range of motion. A useful description of the most common mistakes that may occur when such measurements are included in remote tele-rehabilitation regimes is provided in a recent article on the subject (KarchEáka *et al.*, 2014).

Printers

The ink jet printer head is another example of successful MEMS products. Micro nozzles and channels of 10–20 μm in size are micromachined in an array. A microheater is attached to each channel. The heater generates a bubble in the channel when a current pulse flows through it. An ink droplet is ejected from the nozzle by the pressure pulse caused by the bubble. The amount of the droplet is in the order of a few pL now. A typical head has hundreds of nozzles and channels which operate as fast as 10 kHz. This device takes the advantage of the scaling effect, that is, the speed of heating and cooling increases with decrease in size. Thus, fine pictures and documents are printed on paper. Some heads use piezoactuators and electrostatic actuators to eject ink droplets.

Optical Devices

MEMS is very suitable to optical applications. Light beams can be controlled easily by moving mirrors, shutters, or gratings. MEMS with small feature sizes, precise motion, and arraying capability can realize wide varieties of micro optical MEMS devices and systems based on interference, diffraction and refraction. MEMS technology also enables precisely aligned integration of active and passive optical devices, micromechanical elements and optical fibers. Therefore, optical MEMS devices and systems are used for optical scanners, micro-optical benches, arrayed micromirror displays, optical switches, modulators and attenuators.

The most successful example is a display. An array of movable micromirrors corresponding to pixels reflects light and projects an image on the screen. Each mirror is randomly accessible and tilted either $\pm 10^\circ$ by electrostatic force. The pixel becomes bright or dark depending on the angle of the mirror. The mirror moves within 0.1 ms and controls the brightness by pulse-width-modulation of reflected light. The array is micromachined on top of the IC which allow the individual control of many mirrors within a short time.

MEMS based optical switches have been intensively studied. Optical switches, by means of mechanical movement, have favorable characteristics such as wave-length independence, polarization independence, large contrast, and small crosstalk. 2D MEMS optical switches change the optical path either straight or to a predetermined angle and connect it to one of the two output paths. The typical configuration of an N port 2D MEMS optical switch is shown in Figure 3. Light beams from input optical fibers are collimated by lenses. Micromirrors are inserted at appropriate positions to reflect beams and connect them to the output optical fibers. The alignment between fibers and mirrors is precisely determined by micromachined structures. Arrayed movable mirrors of several hundreds of micrometers in size are driven by microactuators. An on-off motion of the N^2 mirrors is necessary in the switch. The port count, N, is from 2 to 32. For port counts as large as a few hundreds, 3D MEMS switches are used. The schematic configuration is shown in Figure 4. Micromirrors have motion with two degrees of freedom, that is, rotation around two orthogonal axes. Two sets of arrays consisting of N such mirrors are used. Collimated input light beams hit one of the mirrors in the first array that direct the beam to one of the mirrors in the second array. The second mirror reflects the light straight into the output fiber. The

Figure 4 Principle of 3D MEMS optical switch.

analog control of mirror angles allows cross connection of a large number of signals. Those switches have application to optical cross connects, add-drop switches for wavelength divided multiplexing networks, and back-up or inspection apparatuses.

Optical scanners based on movable MEMS mirrors have many applications including bar-code readers, laser range finders, scanning laser microscopes, variable optical attenuators, and laser projection display. Some of them are already introduced in the market.

Chemistry and Biomedical Applications

Handling fluid in micromachined channels offers benefits in chemistry and biotechnology because of the scaling effect. The chemical reaction is completed within a few seconds due to short diffusion time in micro-channels and reactors. Fast and precise temperature control is possible. Arrayed channels allow simultaneous chemical processing of a large variety of reactions. Only a small amount of samples or chemicals are required for chemical analysis and medical diagnosis. Even individual handling and observation of a cell or a molecule has been accomplished.

A typical microchemical chip is composed of one layer having grooves of 10–100 μm in dimension and another layer for sealing and connection to external pipes. Fluids flow in the channel to be mixed, heated, reacted, extracted, separated, and analyzed. Glass and PDMS (poly di-methyl siloxane) are two favored materials for the chip. Applications of microchemical chips include DNA analysis and amplification, blood analysis, environmental monitoring, combinatorial chemical synthesis, bioreactors and sensors, and production of fine chemicals.

The most successful product is the DNA electrophoresis in the micro channel. The device has two orthogonal channels (Figure 5). The sample solution containing DNA that is labeled by a fluorescent dye is introduced in the shorter channel by electro-osmotic effect. A small amount of the sample is injected into the long separation channel by introducing a buffer solution

Figure 5 Principle of a chemical analysis chip based on capillary electrophoresis.

from the end of the other channel. DNA fragments are driven by an electric field in the channel and separated due to the difference in migration speed depending on their length. Separation is completed within seconds and detected by fluorescence.

Future Development of MEMS

The future prospects of MEMS for making contributions to the future society are envisaged in three areas: (1) offering easier access to information for a wider public, (2) making human lifestyles more compatible with the environment, and (3) improving people's social welfare.

Breakthroughs to be accomplished by MEMS would be in five general areas: machine intelligence, downsizing and parallelism, biomimetics, informatics, and environment monitoring/preservation. Downsizing and parallelism will be the direct benefit from miniaturization and multiplicity. Machine intelligence and information networks can be very much improved by introducing MEMS integrated with microelectronics. These breakthroughs are likely to be realized by MEMS technologies within ten years. They may, for example, be used in healthcare for minimally invasive diagnosis and treatment.

Abstract

The chapter titled *Alloys: overview* summarizes general information on metallic materials available in the market and it adds recent findings in new alloys, with a focus on metallic glasses and nanoporous gold, whose applications are of relevant importance in the recent cutting edge technologies.

Key points

- The structural and functional properties of Metallic Alloys are related to their electronic and crystalline structure, as well as to their microstructure.
- Phase Stability and Transformations in Metallic Alloys is ruled by thermodynamic and kinetic factors. The description of the equilibrium phases is reported at constant pressure as composition–temperature plots, known as phase diagrams.
- Depending on their composition, structure and microstructure, Metallic Alloys cover a wide range of properties. An excursus of the principal ones, i.e. mechanical, electrical, magnetic and chemical, are reported.
- Metallic glasses or amorphous alloys are advanced metallic materials characterized by a short-range order atomic arrangement. Usually obtained by rapid solidification of the liquid, they show increased properties compared with their crystalline counterpart.
- Nanoporous metals are promising materials constituted by a scaffold of metallic ligaments and nano-sized porosities; obtained by dealloying of a crystalline or amorphous precursor and thanks to their intriguing properties, they find applications in many technological fields such as catalysts, electro-catalysts, actuators, heat exchangers, energy storage, Raman and SERS substrates.

Introduction

Metallic alloys belong to a fundamental class of engineering materials, with structural and functional properties related to their electronic and crystalline structure, as well as to the microstructure. While structural properties have been usually associated to conventional metallurgy processes, functional properties take part when the alloy microstructure is properly tailored in a micro or nanoscale. In this article, the fundamental aspects of metallic alloys are described and recent findings in the fields of amorphous alloys and nanoporous gold, that might significantly contribute to the cutting edge technologies, are also reported.

Crystal structures in metals and alloys

Chemical bonds and crystal structures

The crystal structure, the chemistry of constituent atoms and the nature of the chemical bonds determine the properties of materials (Christian, 2002). In metals and alloys, atoms are linked by metallic bonds where valence electrons are delocalized over the whole crystal, even if some contributions from covalent and ionic bonds may be observed in special cases. Alkali metals are purely metallic bonded, whereas metals close to metalloids, such as zinc, have increasing covalent bond contributions.

The structure of metals may be described in terms of hard-sphere packing, where non-interpenetrating equal spheres are interconnected to fill the volume as much as possible. Considering a simple layered structure of spheres, hexagonal close-packed (h.c.p.) and face-centered cubic (f.c.c.) crystal structures may be easily built up. On the other hand, considering a slightly lower packing factor, a body-centered cubic (b.c.c.) structure is formed. Furthermore, the allotropy in the metal structure might occur on heating, as observed in iron, which shows a transition from b.c.c. to f.c.c. at 910 °C and a further transition from f.c.c. to b.c.c. at 1400 °C before melting at 1539 °C.

In metallic alloys, the constituent elements may be simply mixed in a solid solution or may form an intermediate phase. In the case of alloys, the difference in electronegativity between constituent atoms becomes the main factor in defining the nature of the chemical bond. In the case of a high difference in electronegativity, an ionic contribution to the chemical bond may be observed. As a consequence, rather complicated crystal structures may be formed. Crystallographic parameters relative to various alloys are available in structural databases.

Solid solutions

Solid solutions may be distinguished as substitutional, when the volume of constituent elements is similar, and interstitial, when a volume difference (size factor) higher than ~15% is observed. A typical example of substitutional solid solution of Zn in Cu is observed in brass, whereas an interstitial solid solution of C in f.c.c. Fe is observed in austenite. Complete solid solubility may be obtained only in alloys when components have the same crystal structure, and the size factor is lower than ~8%. Au–Ni and Ag–Au–Pt are examples of systems showing complete solid solubility.

Sometimes the distribution of atoms in a solid solution deviate from randomness. When similar atoms group themselves preferentially, a clustering effect is observed. On the other hand, when an atom is preferentially surrounded by different atoms, the solid solution is said to show a short-range ordering.

Intermediate phases

When the limit of solid solubility is exceeded on alloying, a second phase is formed. It may be the primary solid solution of the alloying elements, such as in simple eutectic systems, but more often it appears as an intermediate phase. When only metallic components are present in the system, the intermediate phase is called an intermetallic compound.

The simplest intermediate phase is due to long-range ordering of components in the solid solution (ordered phases). In this case, crystallographic positions are preferentially occupied by a specific element, so that an ordering parameter may be defined. Different sub-lattices constituted by single components may be defined in the structure, as evidenced by diffraction techniques. The ordering parameter changes continuously in a limited temperature range, following a second-order thermodynamic transition. Ordering of phases is effective in improving mechanical properties and it is fundamental in superalloys.

When the atoms constituting the intermediate phase show a particular value of the valency electron concentration (e/a), electron phases are formed. For instance, 50% of Zn atoms in a Cu matrix give an electron concentration of 1.50, where a b.c.c. β -phase appears. In the same Cu–Zn system, the complex cubic γ -phase and h.c.p. ϵ -phase are formed for electron concentrations equal to 1.62 and 1.75, respectively. The formation of electron phases is based on the empirical Hume–Rothery's observations, later explained in terms of density of states for valency electrons. Electron phases show a metallic behavior and exist over a range of compositions, such as in brasses and bronzes.

When the intermetallic phase contains a large number of vacant lattice sites, a defect phase may be formed in a limited composition range. Very common intermetallic compounds are known as Laves phases, where the radii of components have the ratio $r_A/r_B = 1.225$, so that a very high packing density is achieved. The interaction of transition metals (M) with small nonmetallic elements (X) generally leads to the formation of interstitial compounds, such as hydrides, borides, nitrides, and carbides. If the ratio between atomic radii r_X/r_M is lower than 0.59, simple compound structures are obtained, where the transition metal forms an f.c.c. or h.c.p. lattice.

In recent years, rather complex intermediate phases have been continuously discovered. Frank–Kasper phases show a huge number of atoms in the unary cell. Quasicrystalline phases show a fivefold symmetry, which was considered forbidden according to the classical crystallographic rules.

Phase stability and transformations in metallic alloys

Thermodynamics and kinetics of phase transformations

Phase stabilities and transformations in metallic alloys are ruled by thermodynamic and kinetic factors. As schematically shown in Fig. 1, in order to transform a phase (a) into a phase (b), a gain in free energy is necessary (Bassani et al., 2005). This free energy

Fig. 1 Free energy as a function of the arrangement of atoms in a phase transformation. Reproduced with permission from Bassani, F., Liedl, G. L. and Wyder, P. (eds) (2005) *Encyclopedia* 1st ed., p. 59.

difference $\Delta G = G_\beta - G_\alpha$ represents the driving force for the phase transformation. The phase transformation becomes possible if the activation barrier ΔG_a is overcome and the new phase is formed at a reasonable rate.

The kinetics of a phase transformation is strongly related to the mechanism. In fact, when the crystallography and/or the chemical composition of the two phases are significantly different, a reconstructive transformation occurs, and a motion of single atoms is necessary. The whole kinetics of phase transformation may be controlled either by the diffusivity or by interface migration. A typical example is given by perlite formation in eutectoidic steels. On the contrary, a cooperative movement of neighboring atoms occurs in displacive transformations, which are diffusionless and generally very fast, because no activation barrier is present. The formation of martensite in steel by quenching represents an example of such a kind of phase transformation.

The kinetics of phase transformation in metallic alloys is often described in terms of time–temperature–transformation curves (TTT), which are a graphical representation of the time necessary to start and to complete isothermally the phase transformation in a specific temperature range. In the case of cooling treatments, continuous-cooling-transformation curves (CCT) are more appropriate. In order to draw thermal treatments in steels, databases of TTT and CCT diagrams are available. The kinetics of phase transformations may be described in terms of the Avrami equation $y = 1 - e^{(-kt)^m}$, where y is the transformed fraction, t is the time, k is a temperature-dependent rate constant, and m is an empirical parameter ranging from 0.5 up to 4, which depends on the type of transformation.

Free energy and phase diagrams

The free energy of a phase depends on several factors, such as composition, temperature, pressure, strain, surfaces, and interfacial energy. In order to define the equilibrium conditions for a generic multicomponent system, the free energy of all phases must be known as a function of composition, temperature, and pressure. The thermodynamic equilibrium is reached when the chemical potential of all elements is the same in all phases (common tangent rule). The number of equilibrium phases is defined by the well-known Gibbs' phase rule and the amount of each phase can be calculated according to the lever rule. The description of the equilibrium phases is generally reported at constant pressure as composition–temperature plots, known as phase diagrams.

In the case of a simple binary metallic system, the equilibrium thermodynamics may be estimated by means of suitable models. For instance, the regular solution model considers only solution phases, where the free energy is described by means of an ideal entropy term and a temperature-independent term for the enthalpy of mixing. This term considers the chemical interactions between the constituent elements, and it turns out positive in the case of repulsion and negative in the case of attraction. When the enthalpy of mixing becomes zero, the solution is ideal. On the basis of the regular solution model, several binary phase diagrams may be calculated, giving solubility or immiscibility either in the liquid or in the solid phases. Examples of phase diagrams calculated with the regular solution model are reported in Fig. 2.

As an example, a full miscibility for the liquid and solid phases is shown in Cu–Ni, simple eutectics are observed in Cu–Ag and in Al–Si, and a single peritectic is observed in Ag–Pt. Intermediate phases are shown in the phase diagrams as single lines (line compounds) or as compounds with limited solubility, such as in bronze and brass.

The equilibrium conditions for a ternary system may be represented by the Gibbs' triangle, where isothermal sections of the phase diagrams are reported as a function of the composition of components. The method for plotting compositions in a ternary phase diagram is shown in Fig. 3. For multicomponent systems, only sections of the phase diagram are usually reported (pseudo-binary phase diagrams). Phase diagrams are generally determined experimentally. Physical properties of alloys with different compositions are followed as a function of temperature, giving an experimental evidence of transition temperatures and equilibrium points. Calorimetric techniques are used for the determination of thermophysical quantities.

Modern computing techniques allow the description of the thermodynamics of multicomponent systems of industrial interest. For instance, by means of the CALPHAD (CALculation of PHase Diagrams) method, the free energy of all phases is described as a

Fig. 2 Examples of binary phase diagrams calculated according to the regular solution model. (a) Ideal solution; (b) Interaction parameter equal to 10^4 J mol^{-1} and $3 \times 10^4 \text{ J mol}^{-1}$ for the liquid and solid phases, respectively. An entropy of melting of $10 \text{ J mol}^{-1} \text{ K}^{-1}$ has been considered for both pure elements. Reproduced with permission from Bassani, F., Liedl, G. L. and Wyder, P. (eds) (2005) *Encyclopedia*, 1st ed., p. 60.

Fig. 3 Representation of compositions for ternary alloys. The vertices represent 100% of A, B, or C. The binary systems are represented in the boundaries of the triangle. Ternary alloys are reported in the middle of the triangle. The distances of the points from the boundaries represent the relative proportions of the components indicated in the opposite vertex of the triangle. The point indicated in the figure indicates the composition with 20% of C, 50% of A, and 30% of B. Reproduced with permission from Bassani, F., Liedl, G. L. and Wyder, P. (eds) (2005) *Encyclopedia*, 1st ed., p. 60.

function of temperature and composition through parameters obtained by an assessment of experimental data and *ab-initio* calculations (Saunders and Miodownik, 1998). Databases of parameters are available for metallic alloys of industrial interest, allowing the calculation of equilibrium conditions, phase diagrams, and thermodynamic quantities.

Microstructure of metallic alloys

Properties of metallic alloys are often related to the microstructure, which depends on phase transformations and mechanical treatments involved in the processing (Davis, 1998; Haasen, 1996). Examples of microstructures are shown in Fig. 4.

Reconstructive phase transformations usually proceed by nucleation and growth mechanisms. In the case of a single phase, the grain size determines the grain boundary area, which affects the strength through the Hall–Petch relationship. Grain size is ruled by solidification rate, plastic deformation, and recrystallization treatments. Eutectic and eutectoid transformations give a lamellar microstructure. The significant composition difference between the parent and the product phases needs atomic diffusion, so the interlamellar spacing is related to the temperature of the phase transformation. As an example, the temperature of thermal treatments in steels defines the final microstructure, ranging from coarse pearlite to fine bainite. Similar fine microstructures may be also obtained by tempering of martensite, previously obtained by quenching. For light alloys, precipitation hardening is related

Fig. 4 Examples of microstructures. (a) Microstructure in spheroidal cast iron: black zone is the nodular graphite, surrounding gray area is ferrite, and the light area is pearlite. (b) Microstructure in eutectic $Pb_{26}Sn_{74}$: white areas are Pb-rich solid solution and dark areas are the Sn-rich solid solution. (c) Microstructure in as-cast $Al_{87}Ni_7Ce_6$: white area is $Al_{11}Ce_3$; gray area is Al_3Ni ; dark area is f.c.c. Al. (Courtesy of Rizzi P, University of Torino, Italy.) Reproduced with permission from Bassani, F., Liedl, G. L. and Wyder, P. (eds) (2005) *Encyclopedia*, 1st ed., p. 61.

to the microstructure. Metastable phases with interfaces coherent to the matrix may be produced by suitable aging treatments of supersaturated solid solutions obtained by quenching. Similar microstructural effects are observed in spinodal decompositions, where composition fluctuations occur up to the gradient of concentration (uphill diffusion). In recent years, very fine microstructures may be obtained by suitable processing, giving nanostructured alloys. As an example, ball milling of metallic powders, electrodeposition or severe plastic deformation of ingots, may give a grain size down to few tenths of nanometers, leading to improved properties with respect to coarse-grain materials.

Properties of metallic alloys

Mechanical properties

Synthesis and processing of metallic alloys is mainly aimed at mechanical applications. In fact, metallic materials show a very broad range of mechanical properties, which may be often modified by suitable thermomechanical treatments. Basic mechanical properties of metallic alloys are generally determined by standard tensile tests, leading to the classical stress–strain curves shown in Fig. 5.

Elastic properties are obtained from the elastic range of a tensile test, and they are mainly related to the composition of metallic alloys. The Young modulus (E) of alloys ranges from ~ 40 GPa for Mg-based compositions up to more than 400 GPa for W and Os. The Young modulus for Al-based alloys is ~ 70 GPa, for Cu based and Ti-based alloys is ~ 100 GPa, and for ferrous alloys is ~ 200 GPa. Metallic alloys have a shear modulus (G) $\sim 3/8$ of E and a Poisson ratio (ν) of 0.33. After thermomechanical treatments and changes of the microstructure, the elastic properties remain rather constant, so that they may be considered an intrinsic property of the alloys. The Young modulus of metallic alloys generally decreases as a function of temperature ($\frac{dE}{dT} < 0$).

The strength and elongation properties may be obtained from the plastic range of the stress–strain curve. The yield stress σ_y represents the transition from the elastic to the plastic regime. It depends on the dislocations mobility, so it can be significantly modified by thermomechanical treatments. The strengthening mechanisms in metallic alloys are related to the hindering of dislocation movements. This goal may be obtained by alloying, because the presence of alloying atoms may generate a stress field. In work-hardening processes, the presence of a high dislocation density leads to an entanglement between crossing dislocations. For precipitation-hardening, widely used in light alloys, the presence of precipitates with interfaces coherent with the matrix produces efficient stress fields against dislocation movements. With the reduction of the grain size, a dislocation pile-up occurs at the grain boundaries and a strengthening in the alloy is observed. For superalloys, a precipitation of the ordered phase may be induced in the disordered matrix, so that dislocations may be blocked at the antiphase boundaries.

Often the yielding point cannot be identified easily, so the stress corresponding to a plastic deformation of 0.2% ($\sigma_{0.2\%y}$) is considered. In the case of annealed low-carbon steels, a nonuniform yield phenomenon may be observed, with the resulting production of Luder's lines at the surface. In this case, an upper- (σ_{uy}) and a lower- (σ_{ly}) yield stress are identified. As long as a uniform plastic deformation acts in the metallic alloys, a hardening effect is observed, according to the general equation $\sigma = K\epsilon^n$ where σ is the true stress, ϵ is the true strain, K is the strength coefficient, and n is the strain-hardening exponent. The last parameter measures the tendency of an alloy to be strengthened as a result of plastic deformation. When the plastic deformation becomes nonuniform, a neck begins to form in the test specimen and an apparent maximum is observed in the nominal stress–strain curve. Necking phenomena are very dangerous for metallic alloys aimed at high-plastic deformation, such as in deep-drawing. Certain metallic materials, under special deformation conditions, behave as superplastic alloys, so they resist necking and show uniform elongations up to 1000 times the normal amount.

Fracture in metallic alloys may be ductile or fragile. In ductile fracture, a significant plastic deformation acts before rupture and a characteristic cup–cone fracture is observed at the surface of the test specimen. Brittle fracture is more dangerous because it happens

Fig. 5 Example of a stress–strain curve for steel (0.4% C, 4% Cr). Basic mechanical parameters are indicated: E , Young modulus; σ_y , yield stress, UTS, ultimate tensile stress, σ_f , fracture stress. Reproduced with permission from Bassani, F., Liedl, G. L. and Wyder, P. (eds) (2005) *Encyclopedia*, 1st ed., p. 62.

suddenly without prior evident plastic deformation. Fracture may be intergranular, when it follows the grain boundaries, or intragranular, when it crosses the interior of the grains. Fracture by cleavage is often observed instead of by shear. A ductile-to-brittle transition may be observed in a limited temperature range by standard impact tests (Charpy type). For instance, for ferritic steels it occurs below room temperature and may be crucial for low-temperature applications. The tendency for crack propagation is defined by the fracture toughness (K_{Ic}). It is obtained from a specific test, where increasing stresses are applied to a pre-cracked specimen. Depending on the mode of loading, different fracture toughness parameters are defined (I, II, and III).

Fracture is generally pictured as consisting of two stages: crack formation and growth. Crack formation may be due to processing or use of the alloy. It generally happens at the surfaces, and it is often related to repeated stresses in the elastic range, a phenomenon known as fatigue. Due to this reason, for metallic alloys it is necessary to define an endurance limit, which is about one half of the tensile strength: below this value, the alloy can withstand an unlimited number of stress cycles without fracture. Unfortunately, some alloys (e.g., Al-based alloys) do not show this limit, so that the fatigue strength must be defined for a given number of cycles.

Hardness of metallic alloys is determined by specific tests, which are based on the resistance to penetration. A commercial hardness tester forces a small sphere, pyramid, or cone into the body of the alloy by means of an applied load. Hardness numbers may be roughly related to tensile strength. When the applied load is small, the hardness may be determined for single phases evidenced in the microstructure of the alloy. For instance, a resolution down to 200 mm may be obtained by the microhardness Vickers test.

For applications at high temperature, the creep phenomena may occur in metallic alloys. They are due to the occurrence of a plastic strain when the alloy is stressed in the elastic regime. Creep is related to dislocations climbing induced by the high temperature. For moderate stresses, grain boundary sliding may even occur, because of atomic diffusion. Creep may be avoided in superalloys, where precipitates of ordered phases hinder the dislocation movements.

Electrical and magnetic properties

Electrical properties of metallic alloys are closely linked to the electronic structure, and the conduction of electrons depends on partially filled bands. According to Mathiessen's rule, the electrical resistivity of alloys increases linearly with temperature near room temperature and above, although the behavior at very low temperature is more complex. Electrical resistivity is strongly enhanced by the presence of foreign atoms in a solid solution in the metal matrix. As an example, the effect of the addition of 0.1 wt% of different atoms in Cu is shown in Fig. 6.

It is clear that the effect is strongly dependent on the electronic configuration of the foreign atom. Oxygen has a very big effect, and, to produce copper wires, oxygen-free material is necessary. Cold rolling increases resistivity only slightly and it is often used as a means for strengthening alloys for electrical conductors. Metallic alloys behave as superconductors only at very low temperatures and they have been fully replaced by high-temperature oxide superconductors for practical applications. Thermoelectric effects of metallic alloys are widely used for devices such as thermocouples, thermoresistors, and Peltier junctions.

The magnetic properties of metallic alloys are of fundamental interest, and they are linked to several industrial applications. The primary applications arise in ferromagnetic alloys, based on Fe, Ni, Co, and some rare-earth metals. On the basis of the values of magnetization induced in the material when subjected to a magnetizing field, represented graphically by the hysteresis loop, ferromagnetic metallic alloys are distinguished in soft and hard magnets.

Soft magnetic alloys are characterized by high magnetic permeability, low coercive field, and low core losses. For these materials, a high saturation magnetization is generally desirable. These materials are suitable for electrical motors, transformers, and relays, because of the fast response of magnetization to the applied magnetic field. In Fe, there is a strong relationship between permeability and crystallographic directions, so that the magnetic flux runs better along the (100) direction (i.e., the edge of the cubic uniaxial cell), giving low-energy losses. For this reason, commercial steel containing 3% Si is processed so that a preferred

Fig. 6 Effect of the addition of 0.1 wt% of various elements in solid solution on the electrical conductivity of copper. Reproduced with permission from Bassani, F., Liedl, G. L. and Wyder, P. (eds) (2005) *Encyclopedia*, 1st ed., p. 62.

orientation of grains is obtained (Goss texture). Amorphous alloys show still lower power losses, and they find applications in small-sized transformers. Magnetic shields may be obtained using materials with very high magnetic permeability, such as Fe–Ni alloys.

On the contrary, hard magnets have a high coercive field and a high saturation magnetization. A parameter representative of the magnetic energy that can be stored per unit of mass is given by the maximum external energy, $(BH)_{\max}$, which is calculated on the demagnetizing portion of the hysteresis loop. These materials are mainly used as permanent magnets, often used to convert electrical energy to mechanical motion (electrical engines) or to convert mechanical motion to electrical energy (microphones). Defects able to hinder the movements of dislocations are usually also able to hinder the movement of magnetic domains, increasing the magnetic hardness of the material. So, high carbon and alloyed steels are often used as permanent magnets. In recent years, new metallic alloys, characterized by a strong magnetic anisotropy in the unary cell, have been developed. These materials contain rare earths as alloying element, such as in SmCo_5 and in $\text{Fe}_{14}\text{Nd}_2\text{B}$.

Chemical properties

Metallic alloys are not chemically stable. In fact, metallurgical processes devoted to the production of metals from their oxides are often counter-balanced by corrosion and oxidation, which progressively transform the metallic alloys in more stable compounds. Corrosion is a wet phenomenon, which is possible only in the presence of humidity. The corrosion resistance of metallic alloys is generally related to the properties of parent elements, according to the electromotive series. A control of the microstructure of the alloys may change the mechanism of corrosion, which should not be localized but uniformly distributed on the whole surface. In several cases, the addition of elements prone to passivity (Cr, Al) is used to increase the corrosion resistance of alloys, such as in the case of stainless steel. Corrosion might be also avoided by deposition of thin layers of a metal on the surface of the alloy, such as in zinc coating and tinning of steel. Oxidation is a high-temperature process, due to the reaction of the metallic alloy with the atmosphere. At the very beginning of the reaction, a thin layer of the oxide is formed at the surface. If the volume of the oxide is at least as great as the volume of the metal from which it formed, the oxide is protective, and oxidation proceeds slowly. On the contrary, if the volume of oxide is less than this amount, the layer is not continuous and it is less effective in preventing the access of oxygen to the alloy surface, so that the reaction rate becomes high. Often the simultaneous formation of two or more oxide layers is observed, such as in steel, where a variable amount of FeO , Fe_3O_4 , and Fe_2O_3 layers are formed at different temperatures.

Materials selection

For specific applications, it is a combination of material properties (material index) that characterizes the performance. Properties of alloys are available in databases, so that merit indices, combined with Ashby's charts (Ashby, 1992), allow optimization of the material selection process.

Advanced metallic materials

Amorphous alloys

The physical properties of metallic glasses or amorphous alloys are determined by a short-range order atomic arrangement. They are usually obtained by rapid solidification of the liquid, which is usually achieved by a melt-spinning apparatus (Fig. 7(a)). The molten alloy is ejected, by a gas overpressure, from a quartz or boron nitride crucible, onto a copper wheel rotating at high speed. The melting is induced by a water-cooled coil around the crucible. The atmosphere in the chamber can be purged and filled with argon, in order to avoid the oxidations during the melting of the alloy or kept in air, depending on the alloy. The copper wheel rapidly transfers and dissipates the heat of the melt that solidify in a ribbon shape.

Fig. 7 (a) Scheme of a melt spinning apparatus. SE-SEM images of an Au-based melt-spun ribbon: (b) details of the air-side, (c) details of the wheel-side.

Process parameters affect the dimension of the ribbon: the size of the crucible nozzle determines the width of the ribbon, the speed of the wheel the thickness (i.e., the higher is the rate, the thinner is the ribbon) and the quantity of the molten alloy the lengths. The speed of the wheel is between 10 and 60 m/s and resulting in a cooling rate of 10^4 – 10^6 K/s. A melt-spun ribbon is characterized by a different finishing on the two sides: the surface that solidifies in contact with the atmosphere of the apparatus (named air-side) is usually wave and shiny, while the side that solidifies in contact with the copper wheel (named wheel-side) is dull and signed by longitudinal roughness due to the surface irregularities of the wheel and cavities when gas bubbles remain trapped during the quenching procedure (Fig. 7(b) and (c)).

During the rapid quenching of the melt, the competition between thermodynamics and kinetics of crystallization forces the system to avoid nucleation. In fact, below the liquidus equilibrium temperature, thermodynamics expects a lower free energy for the crystalline state, involving the movements of atoms into an ordered configuration. As the liquid is cooled down, an increasing of the melt viscosity and a decreasing of atoms mobility occur on undercooling, avoiding nucleation of crystals and promoting glass formation. Since faster is the cooling of the glass, the lower is its density, the melt-spinning process is a key step for metallic glass synthesis. Not all systems are good glass formers and not all compositions are suitable to solidify in the amorphous state. As described empirically by Inoue (Inoue, 2015a,b), multi-element alloys with negative heats of mixing, low temperature of melting from deep eutectics of the binaries, significant difference in atomic size (over $\sim 12\%$) among constituents define the rules of thumb to obtain a metallic glass.

The easiness of a system to solidify in the amorphous state is generally defined as glass forming ability (GFA), and a criterion for its evaluation was proposed by Turnbull in the early 1980s (Wang et al., 2004) by the definition of the reduced glass transition temperature $T_{rg} = \frac{T_g}{T_m}$, where T_g is the glass transition temperature and T_m is the melting temperature of the alloy: if T_{rg} is greater than $2/3$, the alloys have a very slow nucleation and growth kinetics and can be undercooled down to T_g even at low speeds, obtaining a metallic glass. In some cases, a bulk metallic glass can be obtained, i.e., with a thickness of the amorphous material in a certain extent, i.e., from few millimeters to more than one centimeter. A high GFA is linked to a low critical cooling rate, and to a high thickness of the obtained glass.

The history of metallic glasses starts in the 60s of the last century but it still going on. The first metallic glass was synthesized in 1969 by Duwez et al. (Wang et al., 2004; Klement et al., 1960) by quenching an Au-Si molten alloy at very high rates of 10^5 – 10^6 K/s.

A huge number of alloy systems are able to solidify in the glassy state, named accordingly with the element that is in the major content. Formation and characterization of various Zr, La, Mg and Pd based metallic glasses have been reported and efforts are on-going to develop several amorphous systems based on transition metals and rare-earths. Technological importance of metallic glasses covers different field from aerospace to magnetic application, from corrosion resistance to biomedical, from jewelry to sport equipment (Davidson et al., 2013; Hofmann and Roberts, 2015; Khan et al., 2018; Fan et al., 2019; Greer, 2014). For instance, among the zirconium glassy alloys, the first to be marketed under the name of Vitreloy-1 was the quinary alloy $\text{Zr}_{41.2}\text{Ti}_{13.8}\text{Cu}_{12.5}\text{Ni}_{10}\text{Be}_{22.5}$, developed at Caltech. Exploiting the excellent mechanical properties, this alloy was applied for the production of golf and baseball clubs (Telford, 2004).

Au-based amorphous alloys have been explored firstly with the intent of finding new alloys for jewelry application due to the bright surface finishing. The Au-Si system is characterized by a deep eutectic and represents the base for all later Au-based metallic glasses. Remaining on this specific system, such composition has been then modified by adding a third element with different atomic size and crystalline symmetry, with the effect of reducing the melting temperature (Vega and Newman, 2014) and facilitating the glass formation. Increasing the complexity of the alloy, the Au-Cu-Si system has been widely explored to prepare amorphous alloys (Chao et al., 2017; Xu et al., 2018). Moving from the ternary to the quaternary system by adding Ti, the glass forming ability is further increased due to the strong negative heat of mixing with Si and Au. After rapid solidification, the resulting material may be not constituted by a fully homogeneous phase (Fiore et al., 2009; Fiore and Battezzati, 2008) and the matrix may contain quenched-in $\text{Cu}_{15}\text{Si}_4$ crystals (Scaglione et al., 2010). Literature (Schroers et al., 2005) reports a series of compositions with high glass forming ability (maximum sample thickness between 2 and 5 mm) with good processability, high hardness and a gold content of 49 at. %, hallmarked as 18 k gold alloys. The combination of these properties makes the alloys attractive for many electronic, medical and dental applications, as well as for surface coating. In 2009, quinary elements Au-based alloys with low Au concentration ($35 \leq x \leq 50\%$ at. Au) (Guo et al., 2009) were prepared with the aim of exploring the GFA of materials. Among them, $\text{Au}_{40}\text{Cu}_{28}\text{Pd}_5\text{Ag}_7\text{Si}_{20}$ was the one with the best GFA. This composition was further modified by decreasing the amount of gold of 10 and 20 atomic percent and increasing the copper of the same amount (Scaglione et al., 2015b; Xue et al., 2017), obtaining fully amorphous ribbons.

Nanoporous gold

Nanoporous metals are promising materials constituted by a scaffold of metallic ligaments and porosities ranging from nano-size to hundreds of microns. Among them, nanoporous gold (NPG) is certainly one of the most studied. Au-based amorphous alloys have been applied as precursors to synthesize, by selective etching, NPG. Dealloying is the route to obtain such a material. It can be chemical, when driven by the dissolution of the less noble element in a basic or acid solution according to standard potential of elements, or can be electrochemical, when the process is assisted by an applied external potential. During dealloying, the less-noble elements are oxidized as ions in the electrolyte, while the noble ones reorganize, by surface diffusion, in a porous structure made up of interconnected ligaments and porosities. The Fig. 8(a) shows a typical morphology of a sample after dealloying an Au-based amorphous ribbon. Fig. 8(b) reports the cross-section view of the ribbon, after dealloying. The line in the middle has been originated by the process occurred from the external surfaces to the inner of the ribbon when the two dealloying fronts are in touch.

Fig. 8 SE-SEM image of a NPGs by de-alloying an Au based amorphous precursors; (a) top view, (b) cross-section view.

The first NPGs were achieved by dealloying simple binary systems, i.e., Au-Cu (Morrish et al., 2011), Au-Ag (Erlebacher et al., 2001). Aiming to define the basic concept of dealloying, the role of the composition, the critical potential and mechanism associated with the formation of a porous structure have been outlined. In particular, the concept of parting limit considers that the dealloying process is a combined mechanism of dissolution of the less noble elements and surface diffusion of the noble ones. The extent of the porosities inside the bulk of the alloy is limited by the percolation of the electrolyte inside the interconnected pores formed after the oxidation of less noble components in solution. If the less noble components exceed a certain limit concentration, called parting limit, the mechanism proceed gradually in the inner part of the alloy until the sample is fully nanostructured; vice versa below this threshold value, the noble metal is in excess and tends to passivate the surface and dealloying is stopped at the surface sample. For Au-Ag and Au-Cu alloys the parting limit has been evaluated in ~ 45 at. % Au (55 at. % Cu or Ag) and it was shown that this value was close to the percolation threshold for the lattice.

A further step was moving from dealloying amorphous alloys toward to two-component solid solutions, multi-component crystalline alloys, Ag-Au-Pt (Vega and Newman, 2014), Au-Cu-Mn-Zn (Scaglione et al., 2015a), or intermetallic compounds embedded in a solid solution, aimed to achieve a bimodal distribution of ligaments and pores (Zhang et al., 2009; Vukmirovic et al., 2002). Dealloying a crystalline alloy, the original grain is retained in terms of shape and orientation (Van Petegem et al., 2009); while the less noble elements are dissolved in a proper etching solution, the noble constituents, in each grain, reorganize in a structure formed by a network of ligaments of the remaining element. Associated to the dissolution of the less noble components in the alloy, the surface diffusion of the nobler element rules the mechanism of dealloying.

Recently, the advantages to prepare nanoporous metals from amorphous precursors, whose composition conform with the requirements related to the parting limit for dealloying, have been dealt in terms of mechanism of dealloying, morphology of samples and increasing properties compared to crystalline counterparts (Scaglione et al., 2015a). Enhances properties have been ascribed to trapped elements and the rough morphology of ligaments. Indeed, the dealloying of an amorphous precursor together with the dissolution of the less noble element and surface diffusion of gold adatoms involve the nucleation and growth of new crystals that are going to impinge forming multi-grained ligaments.

The scientific interest in these materials has rapidly increased in the recent decades, thanks not only to the versatile sizing of ligaments and pores (Xue et al., 2018) but also due to their intriguing properties addressed to potential applications in many technological fields. Literature reports NPG as a catalyst, electro-catalysts, actuators, heat exchangers, energy storage, Raman and SERS substrates. Such morphology, has been demonstrated, increases the electrocatalytic activities toward several reactions (i.e., hydrogen evolution reaction (Scaglione et al., 2018), methanol electro-oxidation (Xue et al., 2019a; Paschalidou et al., 2016)) and enhance Surface Enhanced Raman Spectroscopy (SERS) performances of substrates prepared with this material, achieving low detection limits of analyte with probe molecules (Xue et al., 2016). Furthermore, this versatile material lends well itself to be functionalized and applied as a platform for bio-sensing application (Scaglione et al., 2019; Xue et al., 2019b).

Conclusion

Main aspects of metallic alloys have been presented. Structural and functional properties related to electronic and crystalline structure of alloys have been highlighted, in connection with their microstructure. Recent findings in the field of amorphous alloys and nanoporous gold have been presented.

Abstract

Iron alloys are arguably the most important class of engineering materials as a huge number of types can be produced by controlling the type and quantity of alloying elements, casting method, thermal and mechanical processing, etc. Factors contributing to the attractiveness of iron as the principal component of many engineering alloys include (Gladman, 1997; Leslie, 1981): the ability to be produced relatively inexpensively; it has a high melting temperature (1538 °C) which allows thermally activated processes over a range of temperatures and it is allotropic thereby allowing its alloys to undergo several useful phase transformations to generate a wide variety of microstructures, and mechanical and physical properties.

Key points

- Iron is a vital base element for generating the most important class of engineering alloy.
- The structures, phase stability and thermophysical properties of iron are key factors in the creation of a vast array of iron alloys suitable for myriad engineering applications.
- Alloying elements in iron have a major impact on final microstructure, properties and applications
- The development of new types of iron alloys and processing routes continues unabated.

Introduction

Iron alloys are arguably the most important class of engineering materials as a huge number of types can be produced by controlling the type and quantity of alloying elements, casting method, thermal and mechanical processing, etc. Factors contributing to the attractiveness of iron as the principal component of many engineering alloys include (Gladman, 1997; Leslie, 1981): the ability to be produced relatively inexpensively; it has a high melting temperature (1538 °C) which allows thermally activated processes over a range of temperatures and it is allotropic thereby allowing its alloys to undergo several useful phase transformations to generate a wide variety of microstructures, and mechanical and physical properties.

Fig. 1 presents a subgroup of a much wider range of commercially available iron alloys (Ferry, 2005). The alloys given in this figure contain carbon, are generally classed as steels or cast irons, and are by far the most widely used iron alloys but it is pertinent to note that many others are also important. Depending on alloying additions and the complexity of the various processing stages,

Fig. 1 Classification scheme for iron–carbon alloys (range is not exhaustive). From Ferry M (2006) *Direct Strip Casting of Metals and Alloys*. Woodhead Publishing UK.

microstructures (and properties) of steels and cast irons vary dramatically, and include one or more of the following phases: ferrite, pearlite, bainite (range of structures), austenite, and martensite as well as second-phase dispersions such as cementite, graphite, intermetallic compounds, and precipitates. However, a detailed treatment of the structure and properties of Fe–C alloys is beyond the scope of this overview.

There are a range of essentially carbon-free iron alloys that also generate microstructures with attractive properties. Examples include Fe–Be and FePt that exploit the martensitic reaction to generate shape memory behavior (Dunne, 2000) and those alloys that exhibit important physical properties such as Fe–Ni invar alloys with very low thermal expansion coefficients and multi-component alloys such as $(\text{Fe}, \text{Co})_{44}\text{Zr}_7\text{Cu}_1\text{B}_{15}$ (HITPERM) and $\text{Nd}_2\text{Fe}_{14}\text{B}$ with exceptional magnetic and magneto-mechanical properties (Jiles, 2003). The ability to generate iron alloys with such a large range of microstructures and properties has resulted in the use of these materials in an enormous number of applications.

The production of iron alloys

Iron alloy components have been produced from the liquid state for many centuries with mass production of steel commencing in the late nineteenth century. Molten steel was traditionally cast into standing molds, but continuous casting was developed in the 1950s which enabled the production of huge tonnages of steel. Most of the world's steel production is now obtained through this casting route. Following casting, as-cast slabs are thermal and mechanical processed to the desired final shape. In the last few decades, however, near-net-shape casting processes have been developed that are capable of producing near-final-shape products directly from liquid with secondary processing such as hot rolling reduced to an absolute minimum. On a reduced scale, there are various types of novel iron alloys produced in the amorphous, nanocrystalline, and intermetallic form. These materials are either manufactured by conventional casting or by rapid solidification processing, spray deposition, mechanical attrition, and sintering or

physical and chemical vapor deposition, etc. Iron alloys produced by these more exotic techniques are generally restricted to specific applications. Recent advances in additive manufacturing technologies such as 3D printing have enabled conventional and more novel iron alloys to be directly net-shape fabricated into complex final shapes and intricate components.

Structure and properties of iron

The production of pure iron is not possible, but numerous studies have been carried out on the properties of high-purity iron. Iron is situated toward the end of the first transition series in the periodic table with an electron configuration $1s^2 2s^2 2p^6 3s^2 3p^6 3d^6 4s^2$. Iron lies at the left of the larger atomic species Co, Ni, and Cu which are known to crystallize with a close-packed structure. To the left of iron are the less-filled states of Ti, V, Cr, and Mn which subsequently crystallize with a body-centered cubic (b.c.c.) crystal structure. Iron lies between these groups of elements and, depending on temperature, may exist either as the b.c.c. structure ($1394^\circ\text{C} > T_\alpha < 912^\circ\text{C}$) or the face-centered cubic (f.c.c.) structure ($912^\circ\text{C} < T_\gamma < 1394^\circ\text{C}$). The high-temperature b.c.c. structure is not expected under normal circumstances but is a result of magnetic energy effects. The b.c.c. structure exists at standard temperature and pressure, but extreme pressures will generate a hexagonal close-packed (h.c.p.) structure (ϵ -iron).

An important difference between α -iron and γ -iron is the structure of their dislocations (Honeycombe, 1985): the Burgers vector of the minimum energy configuration in α -iron is $a/2 \langle 111 \rangle$ and while dislocations can theoretically dissociate into segments of $a/2 \langle 001 \rangle$, the stacking fault energy (SFE) is so high that substantial dissociation has not been observed. In contrast, γ -iron has a relatively low SFE ($< 80 \text{ mJ m}^{-2}$) and dislocations readily dissociate by the reaction $a/2 \langle 011 \rangle \rightarrow a/6 \langle 112 \rangle + a/6 \langle 211 \rangle$, which generates a ribbon of stacking fault. The difference in both crystal structure and SFE of α -iron and γ -iron strongly influences the deformation and annealing behavior of these phases.

Due to the various allotropic transformations in iron ($\delta \leftrightarrow \gamma \leftrightarrow \alpha$), many physical properties, such as specific volume and electrical conductivity, change discontinuously through these critical temperatures. A notable consequence of the f.c.c. $\leftrightarrow$ b.c.c. transformation is the change in magnitude of the self-diffusion coefficient, D , which follows an Arrhenius-type relationship:

$$D = D_0 \exp(Q/RT)$$

where D_0 is a frequency factor that is virtually independent of absolute temperature (T) and Q is the activation energy for self-diffusion. Table 1 shows the values of D_0 and Q for iron and other alloying elements. It is easily shown that the rate of self-diffusion of iron decreases by two orders of magnitude when f.c.c. iron transforms to the more open b.c.c. structure.

Alloying elements in iron

A number of elements are added to iron to produce a variety of alloys with a wide range of microstructures and properties (Fig. 1). Alloying elements have a strong influence on the stable temperature range of b.c.c. and f.c.c. phases. The classic Wever classification (Fig. 2) has shown that most alloying elements fall into four categories with each generating a particular phase diagram. This figure shows that a particular alloying element in iron may either expand the γ -field (austenite stabilizer) or contract this field (ferrite stabilizer). Elements may also form iron-rich compounds that reduce the extent of the γ -field. The overall behavior is a result of the different enthalpies of solution in both the crystal structures of iron which leads to either an increase or decrease of the temperature range in which austenite is stable. Alloying elements can also be grouped into three major classes: those that form interstitial and substitutional solid solutions, and those that are almost completely immiscible with the crystal lattices of iron.

Table 1 Approximate diffusivity of various interstitial and substitutional elements in iron.

Phase	Element	Activation energy, $Q \text{ (KJmol}^{-1}\text{)}$	Frequency factor, $D_0 \text{ (mm}^2\text{s}^{-1}\text{)}$	Temperature range ($^\circ\text{C}$)
α -Iron	Fe	240	200	700–750
	C	80	0.62	700–750
	N	76	0.3	700–750
	Co	226	20	700–790
	Ni	258	970	700–900
γ -Iron	Fe	284	49	900–1050
	C	135	15	900–1050
	Co	364	3000	1050–1250
	Ni	280	77	930–1050

Fig. 2 Classification of iron alloy binary phase diagrams: (A) and (B) austenite stabilizers; (C) and (D) ferrite stabilizers. After Ferry M (2005) *Alloys: Iron*. In: *Encyclopedia of Condensed Matter Physics*, Bassani F, Liedl G, and Wyder P (eds) UK: Elsevier, 46–53.

Interstitial alloys

The elements H, C, N, and O are considerably smaller than Fe and, therefore, tend to occupy interstitial sites in both the lattices of iron. Fig. 2A shows how the γ -field is stabilized for alloys containing interstitial elements since the f.c.c. lattice provides sites of lower strain energy than does the b.c.c. lattice. These elements have a high rate of diffusion in both the crystal structures of iron, particularly in the less densely packed b.c.c. structure, and are considerably more mobile than substitutional elements (Fig. 3 and Table 1). Nevertheless, interstitial elements have low solubility, particularly in α -iron (ferrite), due to the less favorable geometry of the b.c.c. lattice. The solubility of interstitial elements decreases markedly with temperature and obeys a similar relation as diffusivity:

$$C_{\text{Fe-X}}(T) = A \exp(B/T)$$

where A and B are constants and X is either an equilibrium or metastable phase such as graphite, Fe_2B , Fe_3C , and Fe_3N_4 in equilibrium with either ferrite or austenite. Table 2 gives values of the maximum solubility of various interstitial elements in ferrite and austenite which shows that hydrogen has the highest solubility in ferrite which is demonstrated by a small value of the constant, B (not shown). Table 2 also shows that the solubility of C and N in both forms of ferrite are considerably lower than in austenite.

In the Fe–C system, graphite does not usually form in either ferrite or austenite due to its high activation energy of nucleation. The cementite phase (Fe_3C) or other less stable carbides tend to form instead. The difference between the equilibrium Fe–graphite and metastable (constitutional) Fe– Fe_3C phase diagram is shown in Fig. 4, which illustrates the subtle differences in the phase boundaries. Fe– Fe_3C is probably the most important binary system with the following array of characteristics: (1) various types of invariant phase transformations are possible (peritectic, eutectic, and eutectoid) and (2) the solubility of C in α -iron at 727 °C is only 0.022 wt% whereas γ -iron can accommodate 0.77 wt% C at this temperature. Carbon levels below ~2.11 wt% are classified as steels while higher carbon alloys are classified as cast iron. Steels are classified further into hypoeutectoid ($C < 0.77$ wt%) or hypereutectoid ($C > 0.77$ wt%) while cast irons are classified as either hypoeutectic ($C < 4.30$ wt%) or hypereutectic.

Substitutional alloys

There are many substitutional elements that are partially or completely soluble in both crystal structures of iron. Elements with the largest solubility fall close to Fe in the periodic table: Cr, Ni, Co, Mn, and V. A number of elements, such as Ti, Ca, and K, have almost no solubility in iron. For alloying elements with an f.c.c. or h.c.p. structure, the γ -field is stabilized (Fig. 2A and B) whereas the γ -field is reduced by elements that form Hume–Rothery phases with Cu, Ag, and Au (Fig. 2C) or when iron is alloyed with the b.c.c. transition metals V, Ti, Mo, W, Cr, etc. (Fig. 2D). For those elements that restrict the γ -field completely, austenite cannot exist which eliminates the possibility of generating several important decomposition products (pearlite, bainite, or martensite). These alloys are non heat-treatable in the sense that phase transformations cannot be exploited to control the microstructure and properties. To achieve the desired mechanical properties such as yield strength, these alloys must either be work hardened (which can also recrystallize to produce a fine grain size) or elements are used to promote solid solution strengthening. The heat-treatable alloys are far more amenable to strengthening over a wide range by controlling the transformation products during austenite decomposition.

Fig. 4 Schematic diagram of the metastable (constitutional) Fe–Fe₃C and the stable (equilibrium) Fe–graphite diagram (dashed) showing important temperatures and compositions. After Ferry M (2005) *Alloys: Iron*. In: *Encyclopedia of Condensed Matter Physics*, Bassani F, Liedl G, and Wyder P (eds) UK: Elsevier, 46–53.

Most alloys of iron usually consist of a combination of interstitial and substitutional elements which results in various complex interactions involving atom species. For example, the rate of diffusional transformation is usually controlled by the more sluggish substitutional elements (as shown by the lower diffusivity of these elements, Fig. 3) which favors the formation of nonequilibrium microstructures following austenite decomposition. In addition, elements can combine to produce enhanced strengthening by the generation of atom complexes (Mn–C, etc.) in the lattice or from the formation of alloy carbides ([Fe_aX_bY_c...]_{C_j}).

Phase transformations in iron alloys

The allotropic transformations that occur in pure iron can result in a number of important phase transformations in its alloys (Zackay and Aaronson, 1962; Honeycombe and Bhadeshia, 1995). As indicated in Fig. 2, a given concentration of a ferrite stabilizer can eliminate the austenite phase field, whereas an austenite stabilizer will expand this field to allow the alloy to undergo several useful transformations. For example, Fig. 4 shows that a number of transformations are possible in the Fe–C system. The following brief discussion is devoted mainly to this system as carbon is the most important alloying addition to iron.

During solidification, the peritectic reaction can occur over a certain compositional range. For the peritectic composition (0.09 wt% C), the following invariant reaction can occur at 1495 °C: $L \rightarrow L + \delta \rightarrow \gamma$. In this reaction, liquid + δ -iron transforms isothermally to austenite and has several important consequences during continuous casting of steels.

At higher carbon levels, that is, 0.77 wt% C, the eutectoid reaction occurs at 727 °C: $\gamma \rightarrow \alpha + \text{Fe}_3\text{C}$. For slow cooling rates, austenite (0.77 wt% C) decomposes via a diffusional transformation to produce pearlite which is a lamellar structure containing successive layers of ferrite (0.022 wt% C) and cementite (6.67 wt% C). With increasing cooling rate, the formation of diffusional products such as pearlite and ferrite are suppressed thereby generating nonequilibrium microstructures ranging from a series of bainitic structures to martensite.

At very high cooling rates, diffusional transformation products do not form since atomic diffusion is necessary for nucleation and growth of these phases. This results in the formation of martensite; a term not restricted to iron-base alloys but used to define the product of a non-diffusional phase transformation both in metals and ceramics. The martensitic transformation has the following important characteristics: each atom retains its original neighbors and there is no interchange among the atoms; the transformation does not involve individual atomic jumps characteristic of diffusion-controlled and interface-controlled transformations; the reaction is diffusionless which means the martensite product has the same composition as the parent phase. In Fe–C alloys, the martensite transformation generates a hard, brittle phase whereas, for essentially carbon-free alloys, the martensite is ductile.

For very low carbon levels (<0.022 wt%), Fe—C may undergo a series of precipitation reactions after cooling through the solvus where supersaturated carbon in ferrite decomposes at low temperatures to produce a series of precipitates. This can result in considerable hardening that may or may not be useful depending on the desired application of the alloy.

For carbon levels greater than ~ 2.11 wt%, Fe—C undergoes the eutectic reaction: $L \rightarrow \gamma + \text{Fe}_3\text{C}$. At the eutectic composition (4.3 wt% C), liquid iron transformations take place at 1147°C to produce austenite and cementite with subsequent cooling to room temperature promoting additional phase changes. It is well-known that alloying additions such as Si promote the formation of graphite rather than cementite. Similar to steels, cast irons can generate a wide range of microstructures and properties depending on alloying additions, cooling behavior, etc.

It is clear that the transformation products that form during austenite decomposition in iron-base alloys are expected to be diverse and are influenced by a large number of processing and material-related variables. A particular transformation is achieved by the control of the type and quantity of alloying elements, the cooling rate through the transformation range, and thermomechanical treatments prior to or during transformation, etc. In addition to the classic phase transformations associated with Fe—C, several additional transformations are known to occur in iron alloys. The ability of the alloys of iron to undergo such a diverse range of phase transformations is a major factor contributing to their immense popularity as an engineering material.

Thermomechanical behavior

An understanding of deformation of ferrite and austenite is important as these phases undergo a significant amount of plastic deformation during thermomechanical processing, the most common method for producing useful final components (Manohar et al., 2001). During deformation, many microstructural changes occur: the original grains change shape and an internal substructure forms, texture changes take place, precipitation may occur, dynamic recovery (DRV) or dynamic recrystallization (DRX) processes are possible, and the constituent particles may fracture and redistribute. The most notable material factors that affect both the deformation microstructure of iron alloys include SFE, crystal structure, initial grain size and shape, and the size, shape, and volume fraction of a second phase.

Cold deformation

Cold deformation is restricted to low homologous temperatures ($T < 0.5T_m$), where T_m is the absolute melting temperature. During cold deformation of either ferrite or austenite, there is a marked increase in dislocation density resulting in considerable work hardening and grains subdivide in a complex manner to produce a range of features such as a cellular substructure, microbands, deformation twins, deformation bands, and larger-scale heterogeneities such as shear bands (Humphreys and Hatherly, 2004). In high SFE b.c.c. α -iron, slip is the principal deformation process and occurs in the close-packed $\langle 111 \rangle$ direction but the slip plane may be any of the planes $\{110\}$, $\{112\}$, or $\{123\}$. In contrast, γ -iron has a relatively low SFE (<80 mJ m^{-2}) which results in deformation by slip on $\{111\}\langle 011 \rangle$ systems as well as by twinning. The different modes of deformation result in differences in the work-hardening rate of these phases as well as in the development of deformation textures.

Hot deformation

Hot deformation is carried out at $T > 0.5T_m$ and is distinguished from cold working by the absence or near absence of strain hardening and lower matrix dislocation content (Humphreys and Hatherly, 2004). Deformation becomes more homogeneous with increasing temperature with the frequency of microstructural inhomogeneities such as microbands, transition bands, and shear bands reduced considerably. The driving pressure for softening by recovery and recrystallization (either dynamic or static) is the stored energy of deformation. The process of recovery reduces the internal energy of the metal through mechanisms such as annihilation dislocations and their re-arrangement into low-angle grain boundaries.

The relatively low SFE of austenite does not allow for substantial DRV whereas DRV occurs extensively in ferrite since dislocation climb occurs readily and, for a given temperature, the rate of diffusion of iron atoms in ferrite is $\sim 100\times$ greater than in austenite (Manohar et al., 2001). In ferrite, a significant proportion of the stored energy is released by DRV which reduces the driving force for both dynamic and static recrystallization (SRX). Since the reorganization of dislocations is more difficult in austenite, DRX can occur readily. These differences in the dynamic restoration processes generate two distinctive stress–strain (flow) curves, Fig. 5. Deformation of austenite results in an increase in flow stress via work hardening but at a critical strain (ϵ_c), there is sufficient stored energy to initiate DRX which tends to eventually decrease the flow stress since the rate of work hardening is offset by the softening caused by recrystallization. In contrast, extensive DRV in ferrite leads to a balance between dislocation generation and annihilation which rapidly results in a steady-state flow stress. There is also insufficient stored energy to dynamically recrystallize this phase. During hot working, successive cycles of DRX in austenite have the capability of refining the grain size whereas grain refinement in ferrite can only be achieved by SRX.

Fig. 5 Schematic diagram of typical flow curves associated with the hot deformation of ferrite (α -iron) and austenite (γ -iron). After Ferry M (2005) *Alloys: Iron*. In: *Encyclopedia of Condensed Matter Physics*, Bassani F, Liedl G, and Wyder P (eds) UK: Elsevier, 46–53.

Static annealing

The principal material factors influencing static annealing in iron alloys include composition, initial grain size, initial texture, and second-phase precipitates (Humphreys and Hatherly, 2004). Processing variables are also important and include the mode of deformation, strain, strain rate, and temperature of deformation. In general, both SRX and DRX are initiated by nucleation of strain-free grains at microstructural inhomogeneities such as transition bands, shear bands, and grain boundaries. Cold-deformation of fine-grained ferrite results in nucleation predominantly at prior grain boundaries but a coarse grain size results in substantial shear band nucleation, particularly in those iron alloys containing high levels of interstitial elements.

The most desirable nucleation sites in cold-rolled α -iron are grain boundaries as these nuclei often have orientations where $\langle 111 \rangle$ is almost parallel to the normal direction (ND) of the sheet (Ray et al., 1994). This is significant since a strong $\langle 111 \rangle \parallel \text{ND}$ texture in cold-rolled and annealed steels results in superior sheet formability. Austenitic alloys recrystallize in a similar manner to ferritic alloys, that is, nucleation occurs mainly at grain boundaries, but other microstructural heterogeneities characteristic of deformed austenite also play an important role. Due to the physical processes associated with slip and twinning during cold rolling, austenitic alloys do not produce a high fraction of favorable $\langle 111 \rangle \parallel \text{ND}$ nuclei resulting in reduced formability.

Some recent developments in iron alloys

Magnetic alloys

Iron is ferromagnetic below the Curie temperature and these alloys exhibit a remarkably wide range of magnetic properties. Magnetic materials are broadly classified into two main groups with either soft or hard magnetic characteristics (McHenry and Laughlin, 2000; Jiles, 2003). Soft magnetic alloys have high permeability, low coercivity, and low hysteresis loss whereas hard magnetic (or permanent) magnetic alloys have a sufficiently large resistance to demagnetizing fields due to their high coercivity, remanence, and energy product.

Table 3 gives some properties of a select range of ferromagnetic alloys which includes some of the more recently developed alloys that possess either an amorphous, or a nanocrystalline phase embedded in an amorphous matrix. These materials are usually produced as ribbons or fibers by rapid solidification techniques and are often followed by a series of heat treatments. Soft magnetic alloys based on these structures are generally complex and contain elements such as Cr, Mo, and Al and varying amounts of metalloids (B, Si, C, and P) that help to form the glassy phase. These alloys have low anisotropy combined with high resistivity (which reduces eddy current losses) and have high permeability and low power losses. The most widely investigated alloys in this new class of soft magnetic materials are $\text{Fe}_{73.5}\text{Si}_{13.5}\text{B}_9\text{Nb}_3\text{Cu}_1$ (FINEMET), $\text{Fe}_{88}\text{Zr}_7\text{B}_4\text{Cu}_1$ (NANOPERM), and $\text{Fe}_{44}\text{Co}_{44}\text{Zr}_7\text{B}_4\text{Cu}_1$ (HITPERM).

Table 3 Some notable ferromagnetic iron alloys showing typical properties.

Material	Initial relative permeability (μ_0)	Hysteresis loss per cycle (Jm^{-3})	Saturation induction (Wbm^{-2})	$(BH)_{\text{max}} (\text{kJm}^{-3})$
<i>Soft magnetic alloys</i>				
Commercial iron ingot	1.5×10^2	270	2.14

After Ferry M (2005) Alloys: Iron. In: *Encyclopedia of Condensed Matter Physics*, Bassani F, Liedl G, and Wyder P (eds) UK: Elsevier, 46–53.

etc. which are produced by rapid solidification and crystallization annealing to produce a nanocrystalline structure. Compared with more conventional iron alloys, these materials have very high permeabilities and large inductions.

Permanent magnetic iron-base materials include a variety of alloys and intermetallic compounds. The most widely studied materials in recent years are neodymium–iron–boron (Nd₂Fe₁₄B) and iron–platinum alloys. For permanent magnets, a parameter that specifies its performance characteristic, that is, its resistance to demagnetization, is the maximum energy product $(BH)_{\text{max}}$ where B and H are the magnetic induction and magnetic field strength, respectively. To date, the highest values of $(BH)_{\text{max}}$ are obtained in oriented Nd–Fe–B alloys (320–400 kJ m^{−3}) and sintered fine-grained versions of these alloys (~450 kJ m^{−3}).

Shape memory alloys

Iron alloys can exploit the martensitic reaction to enable a component to be deformed at one temperature with subsequent recovery of the original shape upon heating (Dunne, 2000). This so-called shape memory effect (SME) is associated with the ability of some martensites to undergo thermal reversion on reheating which, on a macroscopic scale, corresponds to up to 15% strain recovery. There are various types of SME including pseudoelasticity, one- and two-way shape memory behavior and magnetic field-induced shape memory. Iron-base shape memory alloys are produced either by conventional casting and thermomechanical processing, or mechanical attrition and sintering, or rapid solidification processing. While the various types of shape memory phenomena occur in alloys of the type of Fe–Mn–Si–Cr, FeBe, FePt, and Fe–Pd–Pt, they are largely under development and more work is required to explore the potential of shape memory iron alloys.

Intermetallic compounds

Iron alloys in the form of an ordered b.c.c structure consisting of two simple cubic interpenetrating sublattices (CsCl or B2 structure) are intermetallic compounds based on the stoichiometric ratios, FeCo, FeAl, and Fe₃Al (Munroe, 2000). These materials have received considerable attention in high-temperature structural applications due to their low density, high electrical resistivity, high strength at temperature, and excellent resistance to oxidation and corrosion in various aggressive chemical environments (Munroe, 2000). Such materials are either thermomechanically processed in a manner similar to metals or produced by more novel processing routes. While binary iron-base intermetallics are inherently brittle and have low creep resistance, considerable work is being carried out to improve these critical properties both by alloy design and by carefully controlling the various processing stages.

Direct strip cast alloys

There have been substantial developments in the mass production of iron alloys by direct strip casting (DSC) which produces as-cast strip products of a thickness less than 2 mm (Ferry, 2006). DSC actually dates back to 1846 when Sir Henry Bessemer developed and

Fig. 6 Schematic diagram of Bessemer's twin roll strip caster. After Ferry M (2005) *Alloys: Iron*. In: *Encyclopedia of Condensed Matter Physics*, Bassani F, Liedl G, and Wyder P (eds) UK: Elsevier, 46–53.

patented a twin roll casting machine to produce tin and lead strip products (Fig. 6). However, the numerous challenges associated with strip casting steel on a commercial scale were not resolved until the beginning of the 21st century. Iron alloys produced by DSC include carbon and alloy steels, stainless steel, iron–silicon alloys, and cast iron (Ferry, 2006). DSC often produces a microstructure that is markedly different from the same material produced by conventional casting and thermomechanical processing (TMP). This is a result of the high solidification rates that tend to produce far-from-equilibrium microstructures. By a careful control of casting parameters and alloying additions, as-cast low carbon steel strip can be generated with a final microstructure consisting of one or more of the following phases: martensite, bainite, acicular ferrite, and polygonal ferrite (Ferry, 2006).

Advanced high strength steels

Driven largely by the automotive industry, a range of advanced high strength steels (AHSS) have been developed with unique combinations of high strength and elongation/formability (Matlock and Speer, 2009). These structural steels are designed for two main purposes: (i) improved first is passenger safety – structural components with higher strength and elongation can absorb greater energy with lower intrusion in the event of a crash, and (ii) 'light-weighting' – higher strength components allow thinner sheet to be used that reduces the automobile mass, which is a potent multiplier on the CO₂ emissions during service. When compared with conventional low and high strength steels, AHSS have superior mechanical properties due to their final structure generated by the control of steel composition and processing route. For example, excellent properties can be generated by controlled cooling from the austenite or austenite + ferrite phase fields after either hot rolling or during continuous annealing after cold rolling. Fig. 7 shows the three main types of AHSS. 1st generation AHSS are largely ferritic and include dual phase (DP), complex phase (CP) and transformation induced plasticity (TRIP) steels. 2nd generation AHSS are largely austenitic and include twinning induced

Fig. 7 Tensile strength and elongation combinations exhibited by existing and targeted Advanced High Strength Steels (AHSS): 1st Gen (DP, CP, TRIP); 2nd Gen (TWIP, AUST SS), and 3rd Gen (under constant development). Adapted from Matlock D and Speer J (2009) Third generation of AHSS: Microstructure design concepts. In: Haldar A, Suwas S, and Bhattacharjee D (eds) *Microstructure and Texture in Steels*. London: Springer.

plasticity (TWIP) steels and austenitic stainless steels (AUST SS) and exhibit superior strength/elongation combinations. However, they are expensive due to the large alloying additions (e.g. 20 wt% Mn) needed for stabilizing the austenite phase to room temperature. 3rd generation AHSS are under intense development and are targeted to have strength/elongation combinations significantly greater than the 1st generation but below that of the 2nd generation. The attractiveness lies in their lower cost due to the leaner alloying additions (typically 2–5 wt%).

Additive manufactured alloys

The recent advent and rapid development of additive manufacturing technologies, commonly called 3D printing, has demonstrated huge advantages in processing various metals and alloys, including various iron alloys, into complex net-shape components. Metal 3D printing is usually a layer-by-layer manufacturing process involving the melting of consecutive deposited layers of metal powder on a base (substrate) using either a laser or electron beam. Each melted surface layer usually solidifies rapidly to generate a built component exhibiting novel microstructures and properties. As such, additive manufacturing of iron alloys is a promising and versatile method for producing complex and intricate-shaped components with tailorable microstructures and properties (Haghdadi et al., 2021; Li et al., 2022). Indeed, manufacturing such intricate shaped components by the conventional processing routes described previously is almost impossible. There is currently a massive research and development effort underway on additive manufacturing of new and existing engineering alloys, including most of the iron alloys reported in Fig. 1. 3D printing generates a wide range of microstructures from near-equilibrium to far-from-equilibrium depending on the type of steel and processing parameters.

Conclusion

This brief overview highlights the importance of iron as a vital base element for generating a very broad suite of engineering alloys, often called steels and cast irons, that can be created with selective additions of a combination of certain alloying elements such as C, Mn, Ni, Cr, Mo, N etc. The allotropic transformation of pure iron, in addition to judicious selection of alloying elements, is sufficient to produce an incredibly large variety of microstructures and, hence, property profiles. The microstructures of these alloys were shown to be further modified by myriad secondary processes, such as casting, hot and cold working operations and various other thermomechanical treatments that enables this alloy class to be regarded as one of the most important for modern engineering applications. The future development of new types of alloys and processing methods will undoubtedly broaden the usage of these critical engineering materials.

Abstract

The main classes of iron-based alloys have been summarized in terms of their alloying elements, microstructures, processing routes and properties, concentrating on strength, toughness and magnetic properties. The governing metallurgical principles behind the behavior have also been covered to identify how and why commercial iron-based alloys have been developed and are being improved. Important terminology relating to iron-based alloys commonly used by metallurgists and which will be encountered in further study have been identified to provide a basis for future reading.

Objectives

- Summarize the main range of iron-based alloys (steels and cast irons) commercially available.
- Describe the main microstructural features observed in iron-based alloys.
- Indicate the principal alloying elements used in iron; their effects on phase stability and kinetics of phase transformations; and their influence on properties.
- Introduce the main processing routes used for iron-based alloys and their effects on structure and properties.
- Relate the main mechanical properties (strength and toughness/ductility) to composition, structure and processing; summarize the thermal and magnetic properties of iron-based alloys.

Introduction

Iron is the fourth most abundant element in the Earth's crust, which, combined with its relative ease of extraction and wide range of processing routes and property combinations make iron-based alloys (principally steels and cast irons) the most important class of engineering materials. The use of iron-based artifacts dates back to 1800 BCE and the 'iron age' followed the 'stone' and 'bronze' ages in the classical ages of man. The smelting of iron using coke instead of charcoal by Abraham Darby from the start of the 1700s is a key step in the Industrial Revolution that led to the current global production of nearly 2 billion tonnes of iron and steel annually, which dwarfs that of other metallic alloys (aluminum-based alloys are second with a global annual production of around 60 million tonnes). Although the use of coke to cheaply and efficiently produce iron and steel established the modern steel industry, it now presents a major problem to its future sustainability as the production of iron and steel contributes some 6–7% of the total global annual CO₂ emissions. However, the wide-range of properties available means that iron-based alloys will continue in use for the foreseeable future.

This summary of iron-based alloys aims to briefly introduce the main features and terminology of this class of alloys to act as a basis for further study.

Iron

Iron, atomic number 26, is the central element of the first transition series in the periodic table and has an electronic configuration of $1s^2, 2s^2, 2p^6, 3s^2, 3p^6, 3d^6, 4s^2$. As an element under atmospheric pressure it is stable in the *bcc* (body centered cubic, ferrite) form up to 912 °C above which the *fcc* (face centered cubic, austenite) form is stable. Iron is unusual in that the *bcc* form becomes stable again at temperatures between 1394 °C and the melting temperature (1538 °C). Conventionally, the low temperature *bcc* form is referred to as α -ferrite (δ -ferrite is the high temperature form), while austenite is referred to as γ ; at temperatures of a few hundred K and below the application of high pressures (around 10 GPa) can cause the *hcp* (hexagonal close packed, ϵ) form of iron to form. The atomic radius of iron is 0.126 nm, which allows significant amounts of other alloying elements to be taken into solid solution and so control over the structure and properties of iron-based alloys.

Alloying element behavior in iron

Apart from isolated examples, such as ARMCO[®] iron, which is ~99.85 wt% Fe, commercial iron-based materials are alloyed with a number of different elements, either deliberately added or as impurities from extraction and processing. The exact effects of individual alloying elements on the structure and properties of the iron-based alloy vary, but the types of alloying element and their effects can be grouped into a number of broad groups.

Interstitial alloying elements

Atoms treated as hard spheres in *bcc* and *fcc* arrangements only fill 68% and 74% of the available space leaving spaces or *interstices* between them. These interstices can be bounded by four (tetrahedral) or six (octahedral) iron atoms and contain a spherical space that could accommodate a solute atom provided its radius was small enough, Fig. 1 and Table 1. Atoms in the first and second row

Fig. 1 Schematic diagrams of the *bcc* and *fcc* unit cells showing iron atoms (solid circles); octahedral interstices (open circles); and tetrahedral interstices (open rectangles); (a) octahedral interstices in *bcc*; (b) tetrahedral interstices in *bcc*; (c) octahedral interstices in *fcc*; and (d) tetrahedral interstices in *fcc*. For (b) and (d) the interstices located behind the atoms are outlined in light gray.

Table 1 Radius values of circle just fitting in interstices in iron unit cells along with atomic radii of interstitial atoms at room temperature.

	<i>Octahedral interstice in bcc</i>	<i>Tetrahedral interstice in bcc</i>	<i>Octahedral interstice in fcc</i>	<i>Tetrahedral interstice in fcc</i>
Ideal sphere radius (nm)	0.0196	0.0369	0.0522	0.0286
B atom radius (nm)	0.085	0.085	0.085	0.085
C atom radius (nm)	0.071	0.071	0.071	0.071
N atom radius (nm)	0.065	0.065	0.065	0.065

of the periodic table are of an appropriate (if somewhat too large) size to fit into these interstices. Of these elements B, C and N are the common alloying elements in iron that are taken into solution interstitially. Addition of these elements markedly reduces the alloy liquidus so that complete melting is achieved at much lower temperatures. The atomic radii of these alloying element atoms differ from that of the interstice sphere, [Table 1](#), which causes strain in the surrounding lattice of iron atoms. The size mismatch between C or N and the interstices in austenite is less than in ferrite so that more of these elements can be taken into solution (higher solubility limit), e.g., the maximum solubility of C in ferrite is 0.02 wt%, whereas 2.0 wt% C can be dissolved in austenite in the binary Fe-C alloy system. Defects in the iron matrix have more open structures (grain boundaries) or strain fields associated with them (dislocations) which can offset some of the strain energy around a solute interstitial atom and so C and N concentrations are higher at boundaries and at dislocations (Cottrell atmospheres ([Cottrell and Bilby, 1949](#))) than away from defects. The interaction between these interstitials and dislocations gives a large strengthening effect, which will be covered in more detail later.

In solution, Fe-X (X = B, C or N) bonds exist so that the greater solubility of interstitials in austenite stabilizes that phase relative to ferrite so that as the alloy contains more C or N, the temperature above which the equilibrium structure is 100% austenite (Ae3 temperature) decreases from 912 °C (pure iron) to 723 °C for Fe-0.8 wt% C. Carbon (and nitrogen) are therefore considered to be austenite-stabilizers. The boron atom is smaller than the interstitial space and the Fe-B bond energy is also relatively low so that B in iron-based alloys will lower the liquidus, but has negligible effect on the stability of ferrite and austenite as the effective Fe-B bond distances are relatively large. The more disordered structures in grain boundaries mean that the co-ordination of iron around B can be increased so that most B in solution in iron-based alloys is located at boundaries.

The number of interstitial sites in an *fcc* or *bcc* unit cell is large, [Fig. 1](#), e.g. there are 4 octahedral and 8 tetrahedral interstices in an *fcc* unit cell, while the maximum amount of an interstitial alloying element in solution is around 1 atom per three unit cells. As such, there are always empty interstitial sites available for an atom to move into and the iron lattice distortion required for an interstitial atom to move from one site to an adjacent one is relatively small (a function of the migrating atom atomic radius) so that diffusion of interstitials is rapid with a lower temperature dependence than for non-interstitial (substitutional) alloying elements. The diffusivity (or diffusion coefficient), *D*, of an element can be used as a measure of its ease of motion in the solid state. This is usually represented as:

$$D = D_0 \exp\left(\frac{-Q}{RT}\right)$$

Where *Q* is the activation energy (representing temperature-dependence) and *D*₀ is the pre-exponential factor; typical values are summarized in [Table 2](#). The values are only strictly valid for binary Fe—X alloys, which is reasonable for substitutional alloying elements (see next section), but the presence of strong carbide- and nitride- formers, such as Cr and Nb, can reduce the movement of interstitial alloying elements in more highly alloyed systems.

Table 2 Typical diffusivity parameters for selected alloying elements in iron.

<i>Phase</i>	<i>Element</i>	<i>Activation energy, Q (kJ mol⁻¹)</i>	<i>Pre-exponential factor, D₀ (mm² s⁻¹)</i>	<i>Temperature range (°C)</i>
α-ferrite	Fe	240	200	700–750
	C	80	0.62	700–750
	N	76	0.3	700–750
	Cr	343	3 × 10 ⁶	700–750
	Co	226	20	700–790
	Ni	258	970	700–790
γ-austenite	Fe	284	49	900–1050
	C	135	15	900–1050
	Cr	405	1.8 × 10 ⁶	950–1050
	Co	364	3000	1050–1250
	Ni	280	190	930–1050

Substitutional alloying elements

As atomic number increases, the atomic radius of alloying elements increases so that, for alloying elements commonly taken into solution in iron, the strain energy involved for aluminum and later elements in the periodic table is too great for thermodynamic stability and they cannot be accommodated in interstices. An exception to this occurs for iron-based alloys under intense irradiation, e.g., high neutron fluxes in nuclear reactors, where the atoms are displaced into interstitial sites to give highly energetic and short-lived defects. Under less energetic conditions, these alloying elements are taken into solution by replacing, or substituting for, an iron atom on the *bcc* or *fcc* lattice. As such these are substitutional alloying elements. The solubility limit for these alloying elements depends on the size difference, valency and crystal structure of the alloying element compared with the host iron solvent (Hume-Rothery rules, (Hume-Rothery, 1967)). Thus, the first transition series elements, such as Cr, Mn, Co and Ni exhibit high solubilities, e.g. ASTM Grade HK contains 25 wt% Cr and 20 wt% Ni in solution, whereas the solubility of elements such as Al is limited (~1 wt% in austenite and 11 wt% in ferrite).

The ferrite- or austenite-stabilizing nature of substitutional alloying elements in iron is more varied than for the interstitials, partly because most iron-based alloys contain carbon, which is a strong austenite-stabilizer and elements having strong M-X bonds can precipitate carbo-nitrides at high temperatures (in the austenite field) removing carbon from solution and so de-stabilizing austenite. In this way strong carbo-nitride formers, e.g., Ti, V, Cr, Nb, Mo, Ta and W, are ferrite-stabilizers regardless of whether their stable crystal structure is *bcc*, *fcc* or *hcp*.

For non-carbo-nitride formers, then the situation is little clearer. Elements with a stable *fcc* structure, such as Co, Ni and Cu are austenite-stabilizers. However, Mn has a stable *bcc* structure and is an austenite-stabilizer while Si with a diamond structure (based on interlocking *fcc* unit cells) is a ferrite-stabilizer. The behavior of the alloying elements can be classified into four groupings based on their binary Fe-X phase diagram characteristics (Wever classification (Weber, 1928-1929)).

As for interstitial alloying elements, there are substitutional alloying elements that have limited solid solubility and show a marked tendency to concentrate into the liquid during solidification and to grain boundaries in the solid state. The largely detrimental effects of these elements on mechanical properties means that they are viewed as impurities; arising from coke (S), iron ore (P; this is added as a strengthener in some 're-phosphorized' sheet steels) or scrap (Sn).

As substitutional alloying element atoms occupy an iron atom site in the lattice, their migration can only occur if the iron (or substitutional alloying element) atom on the neighboring lattice site is missing. The absence of an atom on a lattice site is known as a vacancy, which is a thermally-activated defect. The need to generate these defects and the greater distortion of the iron lattice in transitioning the larger substitutional alloying element atom from one site to the neighboring one means that substitutional alloying element diffusion rates are much slower than those for interstitial alloying elements, while their temperature dependence is much greater, Table 2.

Phase transformations and microstructures

Most of the mechanical and some of the functional properties of iron-based alloys derive from the matrix microstructure (fine precipitates will be covered later). In pure iron, the room temperature microstructure will be composed of grains of α -ferrite, whose size would be controlled only by cold rolling and annealing cycles. The fixed point transformation temperatures and need only for iron atom re-arrangement leaves little control of or variation in the microstructure. Alloying to give cast irons or steels allows the microstructure (and, hence, properties) to be controlled and tailored to a much greater extent. This arises through:

- (i) Introducing multiple phase fields on the phase diagram, e.g., in pure iron ferrite would form from austenite on cooling through 912 °C, whereas in alloy steels ferrite and austenite co-exist between Ae3 (temperature above which steel is 100% austenite at equilibrium) and Ae1 (temperature below which steel is 100% ferrite at equilibrium). The microstructure can be manipulated while cooling or holding in this two-phase region.
- (ii) The transformation temperatures, e.g., Ae3 and Ae1, can be controlled by the balance of ferrite- and austenite-stabilizers in solution; an extreme example of this would be the Fe-30 wt% Ni steel, which remains as austenite down to liquid nitrogen temperatures. Alloying therefore opens up a much wider temperature range in which to process and modify the microstructure of iron-based alloys.
- (iii) The presence of interstitial and, particularly, substitutional alloying elements can slow the rate of diffusional transformations, allowing other metastable structures, e.g., bainite and martensite, to form during processing, with transformation occurring below the Ae3—Ae1 temperature range.
- (iv) Precipitates formed at high temperatures, e.g., Nb(C,N), can slow the movement of grain boundaries resulting in finer structures or slow growth of diffusional transformation products. Elements, such as B, that concentrate on grain boundaries can stop these acting as nucleation sites and further slow the formation of diffusional transformation products. Other precipitates can form at lower temperatures to provide strengthening.

The phases possible in iron-based alloys are thus expanded from ferrite and austenite to include pearlite (a mixture of ferrite and cementite (Fe₃C)), the various forms of bainite and the range of martensites (Pereloma and Edmonds, 2012). The conditions under which these matrix phases form are often represented on time-temperature-transformation (TTT) and continuous cooling transformation (CCT) diagrams, Fig. 2. These diagrams have traditionally been determined experimentally, but commercial software has developed to offer these as options.

Fig. 2 (a) Schematic TTT diagram showing transformation start (solid) and finish (dashed) lines; the arrows show two examples of heat treatments covered by this type of diagram, i.e., quench to a given temperature followed by an isothermal hold. (b) The effects of alloying with an α -stabilizer, such as Cr or Mo are shown by the movement to red lines and text. (c) The effects of alloying with an γ -stabilizer, such as Ni or Mn are shown by the movement to green lines and text. (d) The effect of increasing prior austenite grain size is shown by the movement to yellow lines and text. (e) Schematic CCT diagram showing four example cooling curves (i)–(iv); CCT diagrams usually exhibit the final hardness values, which would decrease from Hv(i) to Hv(iv) as martensite is progressively replaced by bainite, ferrite and, finally, pearlite. (f) Arrows showing the effects of α -, γ -stabilizers and increasing prior austenite grain size on a CCT diagram.

Ferrite is generally the highest temperature transformation product, which forms initially on austenite grain boundaries by a diffusional mechanism that involves redistribution of carbon and substitutional alloying elements, e.g. Mn would be partitioned to the remaining austenite along with carbon, whereas Cr would be enriched in the growing ferrite. This phase is variously described as grain boundary, allotriomorphic and pro-eutectoid ferrite; if formed within the bulk of a prior austenite grain and not on the grain boundary, it can be termed idiomorphic ferrite.

Pearlite is the product of a eutectoid transformation which occurs by co-ordinated, simultaneous diffusional formation of ferrite and cementite (Fe_3C). Pearlite is a lamellar structure of alternating plates of ferrite and cementite which grow by carbon diffusion in austenite from ahead of a ferrite plate to a position ahead of the adjacent cementite plate.

As temperature decreases or cooling rate increases the driving force for decomposition of austenite increases so that the need for compositional equilibrium is relaxed leading to displacive + diffusional (bainite) and fully displacive (martensite) transformations. Diffusional transformations relieve strains in the parent phase and so interfacial energy dominates the shapes of the product phase regions, often leading to smoothly curved boundaries. Products of displacive transformations are constrained to lie within a single

austenite grain so that they grow across that grain from one boundary in lenticular units as now a balance of strain and interfacial energies needs to be minimized. Displacive transformations are also referred to as shear transformations as the parent (*fcc*) lattice is sheared to form the product (*bcc*) lattice (some schemes refer to diffusional transformation as civilian and displacive as military to indicate the order involved). The shearing action means that the product contains a high dislocation density.

Bainite (Bhadeshia, 2015) forms initially as a displacive lenticular ferrite sub-unit with no diffusion involved so the ferrite has the same composition as the parent austenite including that of interstitial alloying elements. At the formation temperatures of bainite, interstitial alloying elements can diffuse distances of less than a micron during the transformation, although substitutional alloying elements remain frozen in place. The high strain energy associated with carbon trapped in ferrite provides a strong driving force for the sub-micron diffusion of carbon and its precipitation as iron carbide. Bainite that forms at higher temperatures, e.g., 500–550 °C, is termed upper bainite with carbon diffused to the edge of the ferrite sub-unit as well as formed nanometric-sized iron carbides in a single orientation in the sub-unit. Lower bainite forms at lower temperatures, e.g., 400–450 °C, with more restricted carbon diffusion so that the carbides within the sub-unit are still present, but not those at the sub-unit edge. The transition between the two forms is gradual over the transformation temperature range.

Martensite (Olson and Owen, 1992) is the product of a fully displacive transformation with no diffusion even that of interstitials over sub-micron distances; the martensite is therefore super-saturated with carbon. Lower carbon martensites (<0.5 wt% C depending on overall composition) have a lath sub-structure, but, with increasing carbon content (0.5–1.0 wt% C) the larger strain energy causes the sub-structure to change to twins; at carbon levels of 0.6 wt% C and above the lenticular twinned martensite regions will have some untransformed austenite between them at room temperature. From Fig. 2, different matrix phases and mixtures of phases can be generated from a single composition through the use of different heat treatment temperatures or different cooling rates. This is beneficial as the different phases possess different mechanical and functional properties allowing a range of properties to be tailored from a single composition. One downside of this is that thick sections would experience a variation in cooling rate from surface to center and, along with that, a potential spatial variation in structures and properties. Examples of steel microstructures are shown in Fig. 3.

Categories of irons and steels

Fig. 4 is a concise summary of the major types of commercially-available cast irons and steels. The categorization has arisen mainly from the industrial sector requirements for which the grades were developed (Llewellyn and Hudd, 1998; Honeycombe and Bhadeshia, 1995). Thus, low carbon steels with a ferritic structure would possess relatively low strength (onset of plastic deformation and stress to cause fracture), but good ductility (uniform elongation and thinning when undergoing plastic deformation), which means that flat sheets can be readily be pressed / drawn into complex 3D shapes for automotive structures and packaging applications. Increasing the carbon content (without other alloying element increases) introduces pearlite into the structure, which increases strength, but at the expense of ductility.

As the carbon level approaches 0.4 wt% then joining components by fusion welding becomes increasingly difficult and so various substitutional alloying elements are used to continue increasing strength while maintaining ductility or toughness (energy absorbed in fracture) through grain size refinement and precipitate strengthening (see later). Thus, medium carbon steels tend to be more highly alloyed and would be rolled for plate, thicker sections, beams (long products) or forged; the higher alloy content allows bainite and martensite to be formed in the thicker sections if required.

High carbon steels (0.6–1.2 wt% C) tend to be used in applications where high strength is needed without particularly high toughness, such as railway and tram rails, which are based around 0.8 wt% C with a fully pearlitic structure, that offers good wear resistance. Steels used for drills and other machining bits operate at elevated temperatures (500–550 °C) with high strength, which requires stable precipitates and so these steels would be high carbon (up to 1.2 wt% C) with additions of strong carbide-forming elements (Cr, V and Mo for lower strengths and temperatures; Ti, Ta and W for higher strengths and operating temperatures). These would be shaped and heat treated in the single-phase austenite field before being quenched to a fully martensitic structure before being tempered to precipitate the alloy carbides in a fine ferrite matrix.

The steels summarized above would be shaped by thermo-mechanical methods, e.g. extrusion, rolling, drawing and forging, either hot ($T > 0.6$ of the melting temperature in K) or cold ($T < 0.3$ of the melting temperature in K). Few steels are produced with carbon contents above 1.2 wt% as the property mixes and processing routes offer few advantages until cast iron compositions at around 2 wt% C. The high carbon content means that the fully liquid temperature (liquidus) is between 1150 and 1400 °C so that melting and filling of complex mold shapes is achieved more easily. The high carbon content means that these irons cannot be mechanically shaped without cracking and so the component must be cast to final shape. As the liquid metal will lose heat to the mold as it flows into it, it must be cast at a temperature above the liquidus (superheat) so that it remains liquid until the mold is fully filled. The lower liquidus temperatures of cast irons allow greater superheats to be used without excessive oxidation and loss of material. In early cast irons the carbon was present as coarse (multi-micron) cementite particles in a matrix of pearlite, but the addition of >1 wt% Si converts the cementite into graphite in a connected flake-like form. This did not improve the toughness of the cast iron but the formation of graphite during solidification does involve an expansion that combats the liquid to solid contraction of the iron matrix so that the net volume change on casting is very small. Thus, the mold could be made to the final dimensions

Fig. 3 Example steel microstructures. (a) Allotriomorphic ferrite grains and pearlite colonies (optical micrograph); these are coarse features and the separate lamellae in some pearlite colonies can be resolved, in other colonies the image plane cuts the lamellae at oblique angles so that the lamellae are not resolvable and the pearlite appears darker. (b) Grain boundary ferrite with lower bainite sheaves growing from their interfaces in a matrix of lath martensite; the internal lath structure of the martensite makes it gray and is faintly resolvable after nital etching whereas the finer internal carbide structure of lower bainite makes it appear black. (c) As for (b), but with a longer isothermal hold so that more adjacent lower bainite sheaves form to give colonies. (d) Transmission electron microscope (TEM) image of fine structure of lower bainite (LB) where fine cementite particles in the ferritic lath are in one orientation and upper bainite (UB) where the intra-lath carbides are complemented by carbides on the interface of the lath (inter-lath carbide). (e) TEM image showing fine structures of ferrite, pearlite, lath and twin martensite. (f) multi-oriented fine carbides in tempered lath martensite (Strangwood, 1987).

Fig. 4 Classification scheme for the major iron-based alloys.

of the component. Subsequently small additions of Mg and Ce have been found to change the graphite morphology into spheres (SG iron), which has improved the toughness of these cast irons and formed the development of austempered ductile iron (ADI) along with increased alloying. ADI has lower density than wrought steels and improved vibration damping and so is being used for many gear box casings in wind turbines.

A wide range of stainless steels have been developed principally to develop oxidation-resistant alloys for a range of corrosive environments, e.g., saline solutions and various acids, and shapes, e.g., crevices. The basis for stainless steels is the replacement of a non-protective iron oxide surface layer with a self-healing protective chromia (Cr_2O_3) layer. The stoichiometric nature of chromia means that growth is so slow as to be effectively zero, although increased temperature does accelerate this and the chromia vaporizes at 1000–1100 °C. In order for the chromia layer to be self-healing so that scratches re-form chromia rather than any less-protective oxide, there needs to be a minimum of 12 wt% Cr in solution. This level of Cr would mean that the steel was ferrite from liquid to room temperature (ferritic stainless steel) providing medium strength, but poor ductility. Many applications, e.g., stainless steel knives and automotive trim, require thin sheet and so these are usually made in austenitic stainless steels, which contain sufficient nickel, e.g., 18 wt% Cr, 8 wt% Ni, to stabilize austenite down to room temperature. Carbon is not generally used as an austenite-stabilizer because of the strong carbide-forming nature of Cr as formation of Cr-rich carbides could locally deplete the matrix in Cr so that corrosive attack can take place. This corrosion, being localized, can lead to failure of the component, e.g., perforation of a pipe, for the loss of a small amount of material. The risk of carbide formation is highest in the heat affected zone (HAZ) around fusion welds (material from the component that has not been melted but has been heated up to the melting range) and so this is referred to as weld decay. Stainless steel grades that are weldable will either be L (low carbon) or stabilized where Ti or Nb has been added to combine with any carbon in preference to Cr. Austenitic stainless steels are low strength and so for greater load-bearing capability martensitic or duplex (ferrite + austenite) grades are used. Martensitic grades have reduced Ni content so that the austenite transforms to martensite on cooling to room temperature and an increased C content so that, on tempering, strengthening carbide precipitates form. Higher Cr content is needed to ensure that sufficient is retained in solution after carbide formation. These steels are not readily welded because of the potential for weld decay. Duplex stainless steels are very highly alloyed and are heat treated to give equal fractions of ferrite and austenite with the ferrite distributed as particles in the austenite. The isolated ferrite regions provide strength, while the continuous austenite provides toughness. Duplex stainless steels and the more highly alloyed superduplex stainless steels possess exceptional corrosion resistance particularly against localized corrosion (represented by the pitting resistance equivalence number PREN).

The final example class of steels is that of heat resisting power generation steel, which must combine a number of requirements. The need for higher efficiency is driving increases in steam operating temperatures and pressures which the components must withstand for decades and so both oxidation resistance and creep resistance are required. The steelwork must also retain sufficient toughness at room temperature during its operating lifetime to ensure that brittle fracture does not occur during shutdowns. The large amount of steel needed means that costly alloys, such as superduplex or nickel-based alloys are not economical, which has led to the development of the 9–12 Cr steel grades. These steels can be shaped by hot deformation and welded to assemble items such as heat exchangers, while being able to operate under ultra-supercritical (USC) conditions (566 °C at 24.1 MPa steam pressure to 621 °C at 7.2 MPa steam pressure). The steels are sufficiently alloyed that they form fully martensitic (lath as carbon level is around 0.1 wt%) structures that are tempered to form a fine array of Cr-rich carbides along with nitrides that help increase the creep strength of the steel. During service this structure will overage with the carbides and nitrides coarsening which reduces their strengthening contribution and allows the tempered martensite matrix to coarsen (further weakening it). The steels developed (grades 91, 92 and MarBN) are alloyed and heat treated to reduce these coarsening rates.

The text above and the examples in Table 3 is only a summary consideration of the 1000s of steel and iron grades available, but should provide a foundation for further study in the recommended reading.

Processing

The previous section has provided examples of steel and iron grades identifying some processing influences. Non-scrap iron (Moore and Marshall, 1991) is derived from the blast furnace which is a tower structure which reacts carbon in the form of coke with oxygen injected at the base to generate CO in an exothermic reaction that provides the heat needed to heat the rest of the charge (iron ore and limestone); the rising CO reduces the iron oxide to liquid iron by the overall reaction:

The blast furnace process produce pig iron, which is saturated with C (around 4 wt%) along with some Mn (manganese oxide is present in most iron ores) along with S from the coke and P from the iron ore. While Mn is beneficial, the high carbon content makes the iron unusable, while the S and P compromise the toughness of the alloy. Limestone additions remove most of the oxide impurities from the molten pig iron as a lower density liquid slag layer that floats above the liquid iron. The separation, however, is not perfect and some oxides are trapped in the iron as non-metallic inclusions, which also compromise toughness.

The desired steel and iron compositions summarized in the previous section are achieved by primary and secondary steelmaking processes, which reduce the C and P by blowing oxygen through the liquid iron in a basic converter under conditions that prevent large-scale re-oxidation of the iron. Additions are made to reduce S and to achieve the desired levels of elements such as Mn, Si and Ni in the molten steel, which is usually transferred to a 300–400 t capacity ladle. Elements that readily oxidize, such as Cr, are not effectively added in the converter and so their composition is adjusted in secondary steelmaking in the ladle. Alloying is carried out in the liquid phase, where fluid flow ensures full dissolution and mixing to give a uniform composition.

There is a drive to use more scrap (converters can contain up to 50% scrap which is mixed with molten pig iron) with electric arc furnaces (EAFs) able to melt a 100% scrap load, which should only need modification of the carbon and alloying levels without needing to reduce the very high levels of C from pig iron. The use of scrap should also not have the P and S levels associated with pig iron, but will pick up different impurities, such as Cu and Sn from scrap that can alter the resulting steel properties. Specialist (generally high value) steels such as the 9–12 Cr grades and bearing steels are formulated from melting their constituents in small batches (10s rather than 100 s of tonnes) in vacuum or inert gas furnaces (e.g. vacuum induction melting VIM) that are considered 'clean' melting, i.e., low non-metallic, S and P contents. The ingots resulting from solidification of these casts might be further refined by techniques such as vacuum arc remelting (VAR) or electro-slag refining (ESR). The use of these techniques improves the properties of these steels (not used for cast irons), but with the penalty of small tonnages and high costs (energy and monetary).

The bulk of the 1.6 billion tonnes of steel and iron processed annually comes via the blast furnace and converter or EAF routes and produces liquid of the correct composition that is solidified via continuous casting and (to a much lesser extent) ingot casting. Although the liquid can be considered compositionally uniform, solidification introduces composition variations through macro- and micro-segregation. The degree of segregation in continuous casting is much less than in ingot casting giving final product that has much less scatter in properties. Continuous casting uses a bottomless water-cooled copper mold that produces a continuous strand (that is removed steadily at around 5–8 km h⁻¹) with a square or rectangular cross-section up to 2.5 × 0.4 m in size); ingots typically taper with a base dimension up to 1 × 1 m and height of 2–3 m.

The strand/ingot sizes are suitable for solidification, but final products can be plates/sheets down to less than 1 mm in thickness or complex shapes such as rails so that post-casting processing (Llewellyn and Hudd, 1998) is needed, Fig. 5. Large reductions in thickness would be achieved by hot rolling when the yield stress of the steel is reduced along with the rolling load. Integrated plant would deliver the strand flame cut to slabs directly from the continuous caster to the hot rolling mill; otherwise, and for ingots, castings would cool for storage prior to reheating and then hot rolling. Slabs would only be heated prior to the hot rolling process and would be hot rolled to around 35 mm thickness in a series of rolling passes. During hot rolling, the austenite grains would be deformed and recrystallize, either during rolling (dynamic recrystallization) or between rolling passes (static recrystallization); recrystallization would refine the grain size with the recrystallized grain size being inversely related to the strain imposed, although a

<i>Steel grade</i>	<i>Composition (wt%)</i>	<i>Microstructure</i>	<i>Yield stress (MPa)</i>	<i>Tensile strength (MPa)</i>	<i>Elongation to failure (%)</i>	<i>Comments</i>
Ultralow carbon	0.0024–0.0028C, 0.031–0.069 Ti, 0.07 Mn, 0.007 Si, <0.002 N	Ferrite	100	270	55	Thin (~1 mm thick) strip (Kim et al., 2002)
Low carbon	0.1C, 1.7 Mn, 0.25 Si, 0.02 (Nb + Ti)	Ferrite + martensite	350	600	27	https://ahssinsights.org
Medium carbon	0.4C, 0.55 Mn, 1.0 Ni, 1.25 Cr, 0.3 Mo	Bainite + tempered martensite	1200	1600	12	Weidmann et al. (1990)
High carbon	0.8C, 0.8 Mn	Very fine pearlite	–	3000	1–2	Pearlitic steel wire—patented (Weidmann et al., 1990)
High alloy	18.8 Ni, 10.8 Co, 4.22 Mo, 1 Ti	C-free tempered martensite with intermetallic precipitates	937–2318	1053–2539	16.7–8.0	Properties vary with tempering time and temperature (Sha and Guo, 2009)
Heat resistant steel	0.12C, 8.16 Cr, 0.95 Mo, 0.54 Mn, 0.27 Si, 0.14 V, <0.02 N	Tempered martensite with fine alloy carbide precipitates	>450	600–850	>15	Designed for operation at up to 600 °C (Pandey et al., 2017)
Stainless steel	0.099C, 11.68 Cr, 0.37 Si, 0.4 Mn, 0.4 Ni, 0.0095 N	As-quenched and tempered martensite	303–1127	380–1427	7.0–18.0	Lim et al. (1993)
Stainless steel	0.027C, 17.53 Cr, 12.2 Ni, 2.49 Mo, 1.7 Mn, 0.22 Si, 0.07 N	Austenite	275	570	48	185 GPa Young's modulus (Ganesan et al., 2009)
Stainless steel	25 Cr, 7 Ni, 3.6 Mo, 0.25 N, 0.7 Cu, 0.7 W	Ferrite + austenite	650	840	30	185–205 GPa Young's modulus, superduplex stainless steel (Charles, 1991)
Cast iron (gray)	4.35C, 2.23 Si, 0.4 Mo, 0.079 P, 0.089 S, 0.13 Cr, 0.009 Mo	Flake graphite and pearlite	–	150	1.3	Lian et al. (2020)
Cast iron (ADI)	3.45C, 2.43 Si, 0.089 Mn, 0.06 Mg, 0.061 Cr, 0.024 Ni	Graphite nodules, upper bainite and austenite	640	950	6	60J Charpy impact energy (Refaey and Fatahalla, 2003)
Cast iron (white)	2.45C, 1.33 Si, 0.64 Mn, 0.08 P, 0.08 S	Primary Fe ₃ C in a pearlite matrix	–	572	1.2	8J Charpy impact energy (Hsu et al., 2007)
Cast iron (malleable)	2.45C, 1.33 Si, 0.64 Mn, 0.08 P, 0.08 S	Graphite in acicular ferrite (bainite) and austenite	–	1083	2.5	16J Charpy impact energy—heat treated white cast iron (Hsu et al., 2007)

Fig. 5 Schematic diagram of steel processing route; (a) casting and hot rolling, and (b) cold rolling.

limiting recrystallized austenite grain size can be approached toward the end of the hot rolling passes (Humphreys and Hatherly, 2004). High strength steel grades, i.e., those whose microstructures contain large amounts of pearlite, bainite and/or martensite, need to be shaped hot with any subsequent processing being heat treatment, e.g., quenching and tempering, as the low ductility of these grades prevents significant cold deformation. Hot deformation of steels is usually carried out in air rather than protective atmospheres and so significant oxide scale formation can occur, which produces a rough, dull surface and poor shape tolerance. The oxide scale can be removed by pickling in an HCl-based acid solution, while finish machining would be needed if tight dimensional tolerance and good surface finish is required.

Austenitic steels and steels with majority ferrite structures can be shaped by cold methods to give good tolerances and surface finishes (oxide scale from hot working would need to be removed prior to cold deformation). If the section size is large, then cold working would be difficult, due to the large deformation loads involved and strain variation through the section resulting in spatially varying structure and properties in the final component. Unlike hot deformation, recovery and recrystallization do not occur during cold deformation, so that the steel work hardens. This can be beneficial as it provides a low cost route to yield stress increase without extra alloying. Increased work hardening, however, does reduce ductility and so the cold deformed material is subjected to a controlled anneal to give the desired mix of strength and ductility (in the same way as copper would be supplied in quarter, half and three quarters hard conditions). Annealing would be carried out in a protective atmosphere in order to preserve the good surface finish from cold deformation (Humphreys and Hatherly, 2004). Annealing of cold rolled strip can also lead to improved later formability (Ray et al., 1994). Cold rolled materials (strip) can be annealed in continuous furnaces, which gives much more rapid heating rates ($3\text{--}30\text{ }^{\circ}\text{C s}^{-1}$) and can also include a coating stage, e.g., molten zinc pot for galvanized strip material or polymer coating. Non-continuous product or smaller production runs would need to be batch annealed which is a much slower process as the furnace needs to be loaded cold, evacuated and re-filled with a protective atmosphere and then heated to the annealing temperature ($600\text{--}800\text{ }^{\circ}\text{C}$) before holding for the required time and then cooled to room temperature. The greater thermal mass of the furnace and load compared to a strip of steel means that the heating rate is much less ($\sim 5\text{ }^{\circ}\text{C min}^{-1}$). The longer heating phase allows recovery to occur so that the rate of recrystallization is reduced and, for certain grades, the properties obtained are poorer compared with a continuous process.

Mechanical properties

As noted, steel grades have been developed to achieve required property mixes (Honeycombe and Bhadeshia, 1995) with much of the study of steel metallurgy associated with making that process more reliable and more rapid. Although the required properties may include chemical and functional ones, the majority of steels have been developed on the basis of mechanical properties with achieving higher yield stress and tensile strength without compromising ductility and toughness remaining a principal goal.

Elastic deformation of iron and steel components in service is important and generally should be minimized. The material property representing the resistance to elastic deformation is the Young's modulus, which, unlike titanium-based alloys, is relatively constant for most irons and steels at 210 GPa. The only real difference exists for highly alloyed austenitic stainless steels when the value decreases to around 170 GPa.

Many standards for steel grades are based on values for yield stress (onset of plastic deformation) and tensile strength (stress under which necking occurs leading to final fracture). Both of these values are dependent on the difficulty of dislocation motion (to different extents); in irons and steels there are five principal strengthening mechanisms.

Alloying element atoms, both interstitial and substitutional, differ in size from the sites that they occupy and so introduce elastic strain fields into the iron matrix around the atom in solution. These strain fields interact with the strain fields of the dislocations to provide strength increments that increase with the amount of alloying element in solution; this is solid solution strengthening. The matrix strain and, hence, the strengthening increases with atom size mismatch, but this is self-limiting as the greater the size difference the lower the solubility so, for substitutional alloying elements the extent of solid solution rarely exceeds 100 MPa. Interstitial alloying elements such as C and N have a much larger solid solution strengthening effect, because they are small and mobile enough to move to and occupy the compressive strain field region of dislocations leading to a net reduction in strain and so strain energy. These atmospheres effectively pin dislocations as dislocation movement away from the interstitial atom requires the separate strain fields to be re-established; the energy required is manifested in a higher external stress for yield. This is the basis of the yield point effect in ferritic steels, Fig. 6. Initially, dislocations are pinned by interstitial atmospheres (Cottrell atmospheres previously mentioned) and so require a high external stress to cause movement (as the full dislocation and interstitial strain fields need to be re-established once the dislocation moves away from the interstitial). Once freed from their interstitial atmospheres, however, the dislocations can move under a lower stress giving a plateau on the stress-strain curve until dislocation multiplication occurs to a level at which normal work hardening behavior (see below) is seen. The yield point effect can give unsightly thickness variations (Lüders bands/stretcher marks) when final shapes need low and variable cold deformation strains, e.g., curved car body panels. To avoid this, the strip is rolled to a strain beyond the yield point effect plateau, i.e., into the work hardening regime just prior to stamping or forming (Dieter, 1988).

Once the solubility limit is exceeded, precipitate particles are formed with a range of sizes and spacings. Very fine precipitates (up to ~10 nm) can be coherent with the matrix so that dislocations move through (cut) the precipitates, which have higher modulus than the matrix and create a strain field in the surrounding matrix. Both of these effects increase the resistance to dislocation motion. In irons and steels, fine (Nb,V)(C,N) precipitates tend to be coherent, but larger examples of these and most

Fig. 6 Schematic engineering stress—engineering strain curves for (A) medium carbon engineering steel, (B) low carbon ferritic steel and (C) austenitic steel. The curves are slightly displaced along the x-axis to separate them. The onset of plasticity is shown by the yield stress (σ_y) for A and C, while B shows the yield point effect with an initial upper yield stress (a) followed by a lower yield stress (b), which holds until work hardening starts to dominate at (c). The onset of necking is shown by the tensile strength (TS) points and ductility differences are shown by the % elongation to failure values (% el).

other precipitate types, e.g., cementite and Cr-rich carbides, are incoherent. Dislocations cannot pass through incoherent particles and so must loop around them (Orowan bowing), when the strengthening is proportional to the volume fraction and inversely proportional to the precipitate size (radius). Many strengthening precipitates are used in steels with the most effective being precipitated at lower temperatures, such as VC, Mo₂C, M₂₃C₆ and Fe₃C, particularly from tempering of martensitic structures.

Increasing yield stress by solid solution and precipitate strengthening requires increased alloy additions, but the yield stress of grades with good ductility can be increased by cold deformation as for the yield point effect, Fig. 6. Plastic deformation increases the number density of dislocations in a given volume of metal proportionately with the plastic strain. Dislocations interact with each other impeding the movement of mobile dislocations so an increased dislocation density increases yield stress. However, there is little increase in the tensile strength and the ductility of the alloy decreases as work hardening increases.

Grains are regions of crystalline material in a given orientation and grain boundaries represent the area where these orientations change from one to the next. As dislocations are constrained to move along certain (slip) planes, then they cannot move from one grain to an adjacent one. Additionally, the different grain orientations mean that grains do not all start yielding under the same external stress, but softer orientations yield first and then increasing stress extends yield to other grains eventually giving macroscopic plastic deformation of the specimen/component. When dislocations in a deforming grain meet the boundary with a non-deforming grain they are stopped and pile-up. The pile-up projects a stress concentration into the adjacent (non-deforming) grain with the size of the stress concentration being proportional to the grain size. When the combination of stress concentration and external stress reach a critical value, yield is initiated in the adjacent grain. Thus, smaller grain sizes result in higher strength, described by the Hall-Petch relationship, Table 4.

The aim of many steel grades and processing is to maintain as fine a grain size as possible, which can arise mainly from nucleation of new grains, transformation of the matrix grains or recrystallization. In cast irons and cast steels, nucleation of solid grains from the liquid is often employed with nucleation being enhanced by (i) rapid solidification rates by placing 'chills' in the mold that extract heat more rapidly; (ii) adding inoculant particles (small particles that are solid while the iron and steel are molten) which provide a site from which the solid metal can grow; and (iii) vibrating the casting during solidification which transports solid fragments from the already solidified portion into the remaining liquid where they can grow into new solid grains. During hot deformation of wrought products single grains are deformed, e.g., becoming pancake-shaped during rolling, with a high dislocation density. However, at elevated temperatures the excessive dislocations and their associated strain energy can be removed by nucleation of new (recrystallized) grains—generally several new grains for each original grain, leading to refinement of grain size. As mentioned previously, this recrystallization occurs either during deformation (dynamic recrystallization) or after deformation

Table 4 Summary of strengthening contribution relationships used for iron-based alloys; yield stress and critical resolved shear stress can be related by the Taylor factor (*m*, generally between 2.24 and 3.06); $\sigma_Y = \frac{\tau_{CRSS}}{m}$.

Mechanism	Formula	Parameters	Comments
Peierls-Nabarro stress in pure iron	—	σ_0 (tension) τ_0 (shear)	~50 MPa (Kimura, 1999) ~33 MPa (Caillard, 2010)
Solid solution strengthening	$\Delta\sigma_s = k_{si} \sqrt{C_i}$	k_{si} = solid solution strengthening coefficient for solute, <i>i</i> C_i = concentration of <i>i</i> in solution (at.%)	Assumed additive for multiple solutes (Soboyejo, 2003; Leslie, 1981)
Precipitate strengthening (coherent)	$\Delta\tau_{coh} = k_{coh} \sqrt{r} \bar{f}$	k_{coh} = constant, dependent on precipitate, matrix and composition r = mean precipitate radius $\bar{f}$ = precipitate volume fraction	Often referred to as cutting or shearing of deformable particles (Martin, 1980)
Precipitate strengthening (incoherent)	$\Delta\tau_{ppt} = \frac{G b}{\lambda}$	G = shear modulus (~80 GPa for iron) b = Burger's vector $\left(\frac{a}{2} < 110 > \text{ for } fcc \text{ and } \frac{a}{2} < 111 > \text{ for } bcc; a = \text{lattice parameter}\right)$ λ = mean particle spacing (~)	Often referred to as Orowan looping (Martin, 1980)
Work hardening	$\Delta\sigma_{WH} = \alpha G b \sqrt{\rho_D}$	α = work hardening rate (function of composition and microstructure) ρ_D = dislocation density (length/unit volume or number per unit area)	Dislocation density often related to plastic strain, ϵ_p . (Martin, 1980)
Grain size refinement	$\Delta\sigma_{GB} = \frac{k_{HP}}{\sqrt{D}}$	k_{HP} = Hall-Petch constant (material-specific; ~0.74 MPa $\sqrt{\text{m}}$ for low carbon steel) D = average grain diameter	Hall-Petch relationship, also termed grain boundary strengthening (Hall, 1951; Petch, 1953). Can be applied to different boundary types with different constants, e.g., lath and twin boundaries in martensite
Phase balance	$\sigma_Y = \sum_j f_j \sigma_{Yj}$	f_j = volume fraction of phase <i>j</i> σ_{Yj} = yield stress of phase <i>j</i>	This is a rule of mixtures approach using the known yield stress or calculating it for each phase based on the equations above (Young and Bhadeshia, 1994; Goodall et al., 2018)

(static recrystallization). In hot rolling, the slab being reduced in thickness passes back and forth through a single set of 'reversing' rolls, where the time between forward and reverse passes, determines the time for static recrystallization. After repeated recrystallization during hot rolling the grain size tends to reach a limit for roughly spherical (equiaxed) austenite grains. Cooling on completion of hot rolling (often in a coil for ease of handling) causes decomposition of austenite into ferrite, pearlite, bainite and/or martensite. The limiting, equiaxed austenite grain size leads to a ferrite grain size of around 15–25 μm . Further refinement would require more ferrite grains to form on cooling. Ferrite grains form on austenite grain boundaries and so finer grains require more grain boundary area, which is achieved by not recrystallizing during the final few passes so that the austenite grains are 'pancaked' with a higher boundary area per unit volume than if they were spherical. This approach requires the temperature at which the austenite stops recrystallizing (various measures used such as non-recrystallization temperature— T_{nr}) to be raised into the single phase austenite phase field. Alloying with small amounts of strong carbo-nitride formers, of which Nb is the most potent, results in microalloyed or high strength low alloy (HSLA) steels (Gladman, 1997), which can be rolled to give a final ferrite grain size of 4–7 μm [<https://steeluniversity.org>]. HSLA steels have good strength values for low carbon levels, which means that they can be readily fusion welded.

The final strengthening mechanism is that of phase balance. The matrix phases of irons and steels increase in strength in the general order:

$$\text{Austenite} < \text{ferrite} < \text{pearlite} < \text{bainite} < \text{martensite}$$

Changing the phase balance, by heat treatment allied with composition, as summarized above, can be used to change the strength of the alloy, although higher alloy contents would be needed to achieve phases such as bainite and martensite in thicker sections. The strength of martensite is often too high, when combined with its low ductility and toughness, for service application and so steels with more than a few % of martensite in the structure will be tempered to remove the excess carbon from solution to leave a matrix of fine (sub-micron) ferrite (former martensite laths and twins) containing fine and closely spaced carbide precipitates. Tempering takes place below A_{e1} (typically between 200 °C and 700 °C for a few hours). Tempering at 550 °C and above allows substitutional alloying elements to diffuse so that stronger alloy carbides precipitate (Fe_3C forms at lower temperatures), which gives an increase in strength, known as secondary hardening. Strength decreases and ductility increases with increasing tempering time and/or temperature. Tempering close to A_{e1} can give coarsening of the fine matrix lath structure and is generally avoided if possible. Some lower tempering temperatures are also avoided, due to segregation and possible precipitation of solute atoms (such as S and P) to grain boundaries to give grain boundary failure (reversible and irreversible temper embrittlement).

Strength is usually not the only property needed with minimum toughness often being required as well. Toughness is measured either by a fracture energy (J) at a specified single temperature or over a range, as in the Charpy or Izod impact tests (Dieter, 1988) or by a critical stress concentration factor ($\text{MPa m}^{-0.5}$) to cause a crack to become self-propagating, as in fracture toughness (K_{Ic} testing) (Dieter, 1988). Impact tests are relatively quick and easy to perform whereas fracture toughness testing is more specialized and time-consuming, which makes it less common as a material qualification test. When fracture occurs, the creation of fresh surfaces requires surface energy to be provided and so work is done. The energy involved in creating surfaces is small compared with that associated with plastic deformation. Brittle failure only creates cleavage surfaces and so absorbs little energy, whereas ductile failure where the metal voids and the voids extend and coalesce by dislocation motion absorbs greater amounts of energy and so is much tougher. Increasing strength by restricting dislocation motion will generally come at the expense of toughness. Grain boundaries can divert cracks and so refinement of grain size is the only one of the five mechanisms that can increase strength and toughness.

Features that allow voids (or cracks) to form and propagate more readily, reduce the amount of dislocation motion required to fully separate the sample/component into two and so reduce toughness. In irons and steels, there are two main ways that this occurs. Firstly, as noted above, iron- and steel-making causes non-metallic inclusions, such as oxides, to be trapped in the metallic matrix. These inclusions, being ceramics, are harder and with higher modulus than the surrounding iron/steel. In addition, their lack of metallic bonding can cause the interface between the inclusion and the matrix to be weak. The inclusions generally form at high temperatures in the liquid, where fluid flow allows them to grow rapidly so they are multi-micron in size. On plastic deformation, or in the strain field ahead of a crack/defect, the inclusion does not deform as readily as the matrix and so can crack and decohere accompanied by stress concentration in and work hardening of the metallic matrix so that crack initiation and propagation is accelerated with less plastic strain, i.e., toughness is decreased. The greater the size and number density of inclusions then, generally, the lower the toughness. The second main feature is that of grain boundary embrittlement by elements, such as S and P, that segregate to grain boundaries and weaken the bonding across them. This means that the grain boundaries can separate with very little plastic deformation and the toughness is reduced to that corresponding to just the formation of new surfaces. The iron/steel is now brittle and the process a form of embrittlement (e.g., grain boundary embrittlement or temper embrittlement). Iron- and steel-making has developed to reduce the amount of the impurity or tramp elements (S, P, Sn) and reduce the size and number of inclusions present—the steels have become 'cleaner.' In the case of S, a compromise is made in that the full removal of S is achievable, but expensive and so the Mn levels in the steel are maintained to fully precipitate the S as MnS inclusions; these inclusions do contribute to ductile crack initiation and propagation, but this is far better than the brittle failure associated with S in solution on grain boundaries.

Some rough relationships exist between strength and toughness and other mechanical properties, e.g., increased strength delays the initiation of fatigue cracks on smooth samples while increased fracture toughness permits greater fatigue life in a cracked sample before final failure. A full description of the development of other mechanical properties, such as creep, wear and fatigue resistance, is beyond the scope of this overview, which has aimed to show the approaches generally adopted by the iron and steel industry along with their effects as a basis for further reading.

Chemical properties

The principal chemical property associated with irons and steels is corrosion resistance, such as in the stainless steels noted above. Many structures will be constructed of non-stainless steels and irons and require corrosion protection through:

Coatings—as noted above zinc, polymer and paint coatings can be applied to strip steel after cold rolling and annealing, while other structures would be painted after assembly. Small structures and components can be coated by plasma and electrochemical techniques with chromium to provide a protective chromia surface, although, unlike stainless steels, this not self-healing. Oil and gas pipelines can be coated with polymer-based protective coatings when produced as pipe sections or after assembly in the field.

Iron- and steel-based structures can be electrically connected to sacrificial anodes—metals that corrode in preference to iron—to protect the load-bearing structure. This approach is often used for maritime structure, e.g., oil rigs, where blocks of magnesium are attached to the steel structure. The sacrificial anodes will be consumed during service and so periodic replacement is required.

Large structures, such as pipelines, can also be protected by an impressed current, where the potential of the iron or steel structure is altered to lower the corrosion current. Corrosion rate is also pH-dependent and so pipelines might need differing levels of impressed current as they traverse different soil types with different pHs.

Corrosion behavior is very environment-dependent (e.g., temperature, pH, ion concentrations, partial pressure of oxygen and full or partial immersion) and so the assessment of corrosion resistance is generally made under a limited number of controlled conditions, e.g., seawater is often simulated by 3.5% aqueous NaCl solution, for comparison purposes.

Functional properties

In terms of thermal properties, then low alloy ferritic steels have similar thermal conductivity and expansivity values, Table 5. Highly alloyed steels and cast irons with a significant graphite content will possess different values, which can be further modified if the matrix structure changes from ferritic to austenitic. Thus, austenitic stainless steels have low thermal conductivity and high thermal expansivity, which makes machining more difficult and contributes to earlier thermal fatigue in high temperature plant operations. Alloying of Ni with Fe, however, can reduce thermal expansivity and is the basis of the Invar series of alloys.

The electronic structure of iron with its four un-paired 3d electrons means that it is one of only four ferromagnetic elements. Irons and steels are widely used for their magnetic properties either as metallic alloys, e.g., electrical steel, or compounds, e.g., ferrites and $\text{Nd}_2\text{Fe}_{14}\text{B}$ (Jiles, 2003). Iron-based alloys and compounds are unusual in the range of magnetic properties that can be generated. The formation of balanced magnetic domains means that iron and ferritic steels can show no net magnetic moment. However, in ‘clean’ steels, domain walls move readily under an external field to give a soft magnetic material with a narrow hysteresis loop (low coercivity). This behavior is sought for electrical steels, which are low carbon and low alloy, but contain 3.5 wt% Si, which enhances the magnetization as well as increasing resistivity so that eddy current losses are reduced. This steel finds widespread use as a core for windings in electric motors and transformers as laminates of thin sheet (0.3 mm) formed by cold rolling and annealing. More controlled processing produces Goss textured sheet, where grains are preferentially oriented with the *bcc* cell edge easy magnetization direction ($\langle 100 \rangle$) in the plane of the sheet. Less costly processing produces non-grain oriented (NGO) sheet at the cost of greater hysteresis losses. The drive to increased electrification of vehicles is driving the production of more electrical steel and for greater performance; 6 wt% Si would give better electrical and magnetic properties but the lack of ductility makes processing on an industrial scale too difficult currently.

Increased coercivity, i.e., harder magnetic materials, for iron-based alloys can be achieved by impeding domain wall motion, through finer grains size, dislocation density and, most effectively, by the presence of non-magnetic particles, such as carbo-nitrides. In this way increased mechanical strength (and hardness) is allied with increased magnetic hardness.

Metallic iron-based alloys show a limited maximum magnetic hardness and harder magnetic properties come from Fe-based compounds, such as oxide-based ferrites and one of the hardest magnetic materials, $\text{Nd}_2\text{Fe}_{14}\text{B}$, which require ceramic processing methods, such as powder processing. As for metallic iron-based alloys, refining the grain size of $\text{Nd}_2\text{Fe}_{14}\text{B}$ increases the magnetic moment. These materials are finding increasing use in high torque electric motors and in wind turbines. Table 6 summarizes the range of magnetic properties available in commercial iron-based alloys and compounds.

Table 5 Selected thermal properties of stainless steels (Charles, 1991).

Grade	Coefficient of thermal expansivity (10^{-6} K^{-1})	Specific heat capacity ($\text{J kg}^{-1} \text{ K}^{-1}$)	Thermal conductivity ($\text{W m}^{-1} \text{ K}^{-1}$)
Ferritic	10–12.5	450–480	21–60
Austenitic	16	520–544	15–16
Duplex	13.5–14.5	500–530	17–19

Table 6 Some notable ferromagnetic iron alloys showing typical properties.

Material	Initial relative permeability (μ_0)	Hysteresis loss per cycle ($J m^{-3}$)	Saturation induction ($Wb m^{-2}$)	(BH) $_{max}$ ($kJ m^{-3}$)
Soft magnetic alloys				
Commercial iron ingot	1.5×10^2	270	2.14	
Fe-3Si (oriented silicon iron)	1.5×10^3	40–140	2.0	
Fe-45Si (PERMALLOY 45)	2.7×10^3	120	1.60	
Fe _{73.5} Si _{13.5} B ₉ Nb ₃ Cu ₁ (FINEMET)	5×10^3 – 2×10^5		1.0–1.2	
Fe ₈₈ Zr ₇ B ₄ Cu ₁ (NANOPERM)	1×10^4 – 1×10^5		1.5–1.8	
Fe ₄₄ Co ₄₄ Zr ₇ B ₄ Cu ₁ (HITPERM)	2×10^3 – 3×10^4		1.6–2.1	
Hard magnetic alloys				
Fe-1Mn-0.9C (martensitic)				3.8
Fe-3.5Cr-0.9C-0.3Mn (martensitic)				5.0
Fe-24.5Co-13.5Ni-8Al-2Nb (Alnico-XII)				76.8
Fe ₆₀ Pt ₄₀				120
Nd ₂ Fe ₁₄ B (oriented)				320–400
Nd ₂ Fe ₁₄ B (sintered nanophase)				450

Conclusion

The structures, processing and properties of iron-based alloys have been briefly covered along with the main strategies used to achieve the property mixes offered by this class of alloys. This is not comprehensive or very detailed, but should provide a basis for more informed further study.

Alloy and process development of iron-based alloys continues to improve property mixes as well as improve efficiency. These traditional improvements are being modified by the need for more sustainable iron and steel production, i.e., reducing the carbon footprint of the iron and steel industry, while future electrification is providing more applications for iron-based materials with improved functional properties.

Abstract

Mg is an abundant and attractive metal, and it can be used for many energy-efficient and environmental-friendly applications in transportation, communication, hydrogen storage and biodegradable products sectors. Considerable efforts have been made in the past 20 years for wider applications of magnesium alloys, and a remarkable progress is achieved on the design and development of cost-effective alloys with improved properties. A significant achievement is also made for the fundamental understanding of alloy microstructures, deformation mechanisms, precipitation processes, alloying effects on formability, and processing-microstructure-property relationships.

Introduction

Magnesium is the lightest of all commonly used structural metals. It has a density of 1.74 g cm^{-3} at 20°C , approximately two-third that of aluminum and quarter that of steels. It is the eighth most abundant element in the earth's crust, the third most plentiful element dissolved in seawater, and the seventh most abundant element by mass in the human body. It is extracted from seawater, lake brines, dolomite, magnesite and other minerals, and commercially available with purity exceeding 99.8%, but is rarely used in engineering applications in unalloyed form. Magnesium has a relatively low melting temperature (650°C) and high specific heat, [Table 1](#). Therefore, magnesium can be cast readily to near-net shape by conventional casting methods, especially by pressure die casting. Magnesium can also be machined readily, with approximately 55% of the power required to machine aluminum and its alloys. Magnesium alloys have the highest specific stiffness and strength of all structural alloys, making them potentially suitable for automotive applications in which large components, presently fabricated from steel, can be advantageously replaced with this much lighter metal. Magnesium is the third most commonly used structural metal, after aluminum and iron.

Magnesium was first recognized by Joseph Black in 1755 as a new element whose oxide was magnesia (magnesium oxide, MgO). It was first isolated by Humphry Davy in 1808 by evaporating the mercury from a magnesium amalgam that he made by electrolyzing a mixture of wet magnesium oxide and mercuric oxide. Davy suggested a name magnium, but magnesium is the one used nowadays. This name come from Magnesia, a district in Thessaly of Greece where the magnesia was first found. In 1828

Fig. 1 World production of magnesium in the period 1999–2021.

Antoine Alexandre Brutus Bussy isolated the magnesium metal by fusing dehydrated magnesium chloride with metallic potassium at elevated temperatures. The first production of magnesium was made by Michael Faraday in 1833 through electrolytic reduction of dehydrated magnesium chloride. Robert Wilhelm Bunsen made a commercial quantity of pure magnesium in 1852 from molten dehydrated magnesium chloride. The commercial production of magnesium metal on a larger scale started in 1886, reached 10 t per annum in 1890. It was increased to about 3000 t per annum at the end of World War I, and 300,000 t late in World War II. The global commercial production of magnesium metal was around 250,000 t per annum between 1970 and 1999, approximately 368,000 t in 2000, but rose rapidly to around 757,000 t in 2010, reached about 1,000,000 t in 2020, Fig. 1. China now produces about 85% of the global production of magnesium metal.

Magnesium metal is currently produced by completely different processes. One is electrolysis of magnesium chloride the operates in the liquid state, the other is Pidgeon process which involves solid-state thermal reduction of magnesium oxide by ferrosilicon at high temperature. The electrolysis process, adopted by Norsk Hydro and Dow Chemical Company in the past, used to account for 75% of the global production of magnesium. It is environmentally friendly, but its energy consumption is costly. The Pidgeon process is less efficient than the electrolysis, but became dominate since 2000, when China became the major producer of magnesium, where the low cost of labor, energy and ferrosilicon allowed this process to be economically competitive.

In 2021, about 45% of the global magnesium was used to produce light weight magnesium products for applications in the automotive, electronic and aerospace industries, nearly 35% was consumed as an alloying element in aluminum, 16% was used to desulfurize steels, and 4% was used to refine titanium sponge and to produce nodular cast irons, Fig. 2.

Overview

Deformation mechanisms

Magnesium has a hexagonal crystal structure with a c/a ratio of 1.623 at 25 °C. Its close-packed plane is (0001), and its close-packed direction is $\langle 11\bar{2}0 \rangle$. Perfect dislocations include those with Burgers vectors in the basal plane ($1/3 \langle 11\bar{2}0 \rangle$, or $\langle a \rangle$ type), Burgers vectors perpendicular to the basal plane ($[0001]$, or $\langle c \rangle$ type) and Burgers vectors in a pyramidal plane ($1/3 \langle 11\bar{2}3 \rangle$, or $\langle c + a \rangle$ type). Imperfect dislocations include those having a Shockley partial type Burgers vector ($1/3 \langle 10\bar{1}0 \rangle$) on the basal plane, a Burgers vector perpendicular to the basal plane ($1/2[0001]$), or a Burgers vector in a pyramidal plane ($1/6 \langle 20\bar{2}3 \rangle$). Stacking faults include intrinsic faults I_1 and I_2 , extrinsic fault E and twin-like fault T_2 (Chetty and Weinert, 1997). Basal slip can be activated at very low stress at room temperature and is a major deformation mode. Non-basal slips, such as pyramidal I $\{10\bar{1}1\}\langle 11\bar{2}3 \rangle$ and pyramidal II $\{11\bar{2}2\}\langle 11\bar{2}3 \rangle$ slip and prismatic slip can also occur at room temperature, but at much higher stress. The basal and non-basal slips

Fig. 2 Breakdown of global usage of magnesium in 2021.

often occur together in polycrystalline magnesium alloys to allow individual grains to plastically deform to meet the shape change imposed by their neighboring grains (Partridge, 1967; Agnew, 2012). Apart from dislocation slip, twinning is another important deformation mode. The twinning modes include those leading to twin formation on $\{10\bar{1}1\}$, $\{10\bar{1}2\}$, $\{10\bar{1}3\}$, $\{10\bar{1}4\}$, $\{10\bar{1}5\}$, $\{30\bar{3}4\}$, $\{11\bar{2}1\}$ and $\{11\bar{2}4\}$. The $\{10\bar{1}2\}$ extension twin occurs most frequently, and it forms under the stress condition that favors an extension along the c -axis. The formation and growth of $\{10\bar{1}1\}$ contraction twin cause a contraction along the c -axis.

Under an applied external stress σ , the resolved shear stress along the slip/twinning direction on the slip/twinning plane, τ , is given by $\tau = \sigma \cos \alpha \cos \beta$, where α is the angle between the applied stress axis and the slip/twinning direction, and β is the angle between the applied stress axis and the slip/twinning plane normal. The orientation factor, $\cos \alpha \cos \beta$, is also known as Schmid factor, and it is an important parameter for plastic deformation of highly textured polycrystalline magnesium alloys. The resolved shear stress must be larger than a critical value, the critical resolved shear stress (CRSS), in order to activate slip or twinning. The CRSS values for basal and non-basal slips and twinning modes in pure magnesium are provided in Fig. 3 (Nie et al., 2020). Pyramidal slip is more difficult to activate than basal slip, and the activation of contraction twinning needs a higher CRSS than that of extension twinning. CRSS values for basal slip and extension twinning are almost temperature independent, in comparison with others deformation modes whose CRSS values decrease significantly with increasing temperature. Since CRSS values for dislocation slip and twinning are all low, it is a common practice to thermomechanically process magnesium alloys at warm to high temperatures in order to maximize deformation modes to facilitate plastic deformation. Additions of alloying elements or solute atoms can increase or decrease CRSS values, and hence influence the plastic deformation process. Additions of specific alloying elements can also change the recrystallization texture of thermomechanically processed magnesium alloys.

In addition to intra-granular deformation modes of slip and twinning, inter-granular deformation such as grain boundary sliding can also occur, especially when the grain size of polycrystalline pure magnesium is reduced to the vicinity of 1 micron. Less studies have been made on grain boundary sliding in magnesium alloys, mainly because this deformation mode is thought unlikely to occur in wrought magnesium alloys produced by conventional processing methods in which the grain size is usually above 5–10 μm .

Dynamic recrystallization generally does not occur during plastic deformation of magnesium alloys at room temperature, but it plays a major role in texture formation during hot deformation of magnesium alloys. Factors influencing the size and orientation of fully recrystallized grains are temperature, strain, strain rate, solutes, and second-phase particles. While it is now well known that some specific alloying elements can change recrystallization behavior and texture, even at remarkably low concentrations, the precise role of such alloying elements in texture changing remain to be revealed.

Designations of alloys and tempers

Magnesium alloys are commonly designated by the American Society for Testing Materials. One or two letters are generally used in this designation system. The first letter indicates the major principal alloying element, and the second letter represents the next principal alloying element that is in less quantity. These two letters are listed alphabetically when the added two alloying elements are equal in quantity. The code used for alloying elements is the following: A—aluminum; B—bismuth; C—copper; D—cadmium; E—rare earths; F—iron; H—thorium; J—strontium; K—zirconium; L—lithium; M—manganese; N—nickel; P—lead; Q—silver; R—chromium; S—silicon; T—tin; V—gadolinium; W—yttrium; X—calcium; Y—antimony; Z—zinc. These two letters (or one letter) are followed by two (or one) numbers that indicate the weight percentages of these principal alloying elements, rounded off to the nearest whole number. For example, AZ91 represents the alloy Mg-9Al-1Zn-0.3Mn (wt%) in metallurgical notation. The composition of this alloy is (90Mg, 9Al, 1Zn, 0.3Mn, wt%) in which the actual concentration may vary in the range 8.3–9.7 for Al and 0.4–1.0 for Zn. More letters and numbers are added when the alloy contains more than two intentionally added elements. A suffix letter A, B, or C, etc. may also be used for some alloys, and they refer to variations in composition within the specified range. For example, the suffix letter E in higher-purity AZ91E indicates that the concentrations of impurity elements Fe, Ni and Cu, which

Fig. 3 Critical resolved shear stress (CRSS) values for different slip and twinning modes and their variation with temperature for pure Mg single crystals (Nie et al., 2020). From Nie JF, Shin KS, Zeng ZR (2020) Microstructure, deformation, and property of wrought magnesium alloys. *Metallurgical and Materials Transactions A: Physical Metallurgy and Materials Science* 51: 6045–6109.

are detrimental to the alloy corrosion resistance, are lower (Fe 0.015 wt% max., Ni 0.001 wt% max. and Cu 0.015 wt% max.) than those in a less-pure alloy AZ91C. Some magnesium alloys may be used in the heat-treated or work-hardened conditions, i.e., tempers. The temper designations for magnesium alloys are specified in the same way that has been adopted for aluminum alloys. Commonly used tempers are T5 (alloys artificially aged after casting), and T6 (alloys solution treated, quenched and artificially aged).

Processing of magnesium alloys

Alloying

Alloying elements are added to molten magnesium in conventional productions. The intentionally added alloying elements are usually in the form of pure elements or master alloys, and most of them have appreciable solubilities in molten magnesium. One exception to this is beryllium that is usually added at a ppm level which, while being substantially low, is sufficient to reduce the oxidation rate of molten magnesium. The magnesium oxide layer that forms on the molten magnesium does not provide efficient barrier to further oxidation. Molten magnesium ignites and burns when it exposes to air. It is for this reason that the molten magnesium, which is associated with the melting operation in foundry, needs to be covered by a protective gas, which has been 0.2% SF₆, or 0.5–1% SO₂, in dry air. Sulphur hexafluoride was the commonly used component of the cover gas in the past, but the environmental legislations in many countries have eliminated the use of this gas because of its extremely high global warming potential. Sulphur dioxide has a zero green-house potential, but it is a toxic gas and has to be used at a low concentration in the foundry. An alternative cover gas, which uses a low concentration of HFC-134a in nitrogen, carbon dioxide, or air, has been commercially developed in recent years.

For the purpose of corrosion resistance, it is necessary to control the concentration of impurity elements iron, nickel and copper to the ppm level in the cast product. For magnesium alloys that are free of zirconium, manganese is often added to the molten alloy to react with iron to form intermetallic compounds that settle down to the crucible bottom before the molten alloy is cast. In this way, the concentration of iron in the cast alloy is usually less than 40–50 ppm. For magnesium alloys that contain additions of zirconium and/or rare-earth elements, the iron content can be reduced to the ppm level by these elements reacting with iron to form intermetallic particles that are excluded from the casting.

Casting

Magnesium alloy products can be readily produced by conventional casting processes such as high-pressure die casting (HPDC), sand casting, permanent mold casting and thixo-casting. HPDC includes both hot-chamber and cold-chamber processes. In each of these processes, molten alloy is injected into a near-net-shape and smoothly finished cavity within seconds under high pressure. Products with thin walls can be cast by these processes due to the excellent fluidity of molten magnesium alloy, and most HPDC magnesium products do not need to have any post-casting machining. Most automotive and electronic components made of magnesium alloys are produced by HPDC. The most commonly used magnesium alloy for this process is AZ91. This alloy is cast at a temperature in the range 620–640 °C for hot-chamber HPDC, and 650–680 °C for cold-chamber HPDC. Alloys containing less contents of aluminum, such as AM60 (93.7Mg, 6Al, 0.3Mn, wt%), are generally cast at slightly higher temperature. The HPDC magnesium alloys are generally not heat treatable. This is because the gas or air bubbles trapped inside the casting will cause surface blistering or even distortion of the casting if it is heat treated at high temperatures. The casting generally has adequate strength in the as-cast state due to the presence of finer grains and second-phase particles resulting from fast solidification rate of the HPDC processes. A key requirement for the major alloying elements in magnesium die cast alloys is that the addition of such elements should enhance the fluidity of the molten magnesium. Such elements do not need to have appreciable reduction in their equilibrium solid solubilities with temperature that is required for precipitation hardening that is needed for sand castings. Some recent studies demonstrate that it is possible to heat treat HPDC magnesium alloys for a relatively short duration at high temperatures without causing any problem of surface blistering.

Sand casting and permanent mold casting are used to produce magnesium products that are not suitable for HPDC or require mechanical properties for specific applications. As casting is made by pouring molten alloy from the top the mold or pushed from the bottom of the mold with a low-pressure, the solidification rate is much lower than that associated with HPDC. Consequently, the casting has a much coarser grain size and a relatively strong solute segregation (thus non-uniform distribution of the added alloying elements), and its mechanical properties are not sufficient for final applications in the as-cast state. The casting needs to be heat treated in the T6 condition in order to meet the application specifications. The purpose of the T6 temper is to generate a denser and uniform distribution of nano-scale precipitates to make the casting stronger. To avoid the formation of coarse dendrites in the casting, grain refiners are often added to the molten alloy before casting. The most effective grain refiner for magnesium alloys is zirconium, which is often added in the form of a Mg-Zr master alloy. The magnesium-rich side of the binary Mg-Zr phase diagram is peritectic, and at temperatures below 862 °C, the crystal structure and lattice dimensions of zirconium are very similar to those of magnesium. The remarkable grain refinement made by zirconium is mainly through heterogeneous nucleation of magnesium on undissolved Zr particles and stronger restriction to the growth of magnesium grains imposed by the dissolved Zr in the molten alloy (StJohn et al., 2005). While zirconium can provide significant grain refinement and lead to the formation of fine and equiaxed grains, its addition increases the alloy cost. Well-known magnesium alloys for sand casting are WE54 (90.55Mg, 5Y, 2Nd, 2HRE, 0.45Zr, wt%, where HRE represents heavy rare-earth) and WE43 (92.55Mg, 4Y, 2Nd, 1HRE, 0.45Zr, wt%) that were developed for elevated temperature applications. A key requirement for the major alloying elements in magnesium alloys for sand casting is that they should have significant reduction in their equilibrium solid solubilities with temperature that is necessary for precipitation hardening, in addition to their beneficial effects on the fluidity of the molten magnesium.

Thermomechanical processing

After melting, alloying, casting and homogenization, billets of magnesium alloys are hot extruded. The billets for extrusion are typically 150–550 mm in diameter, preheated to 300–450 °C, and extruded at a speed of 0.5–30 m min⁻¹ into solid or hollow profiles of various shapes by direct extrusion that is commonly used by the industry. The profiles are straightened in the extrusion direction after the extrusion to remove the residual stress, to improve mechanical properties, and to meet the required straightness. For the profiles that are made of age hardenable magnesium alloys, they are usually cooled rapidly by forced air after exiting the die and subsequently aged at a temperature in the range 100–200 °C to further increase their strength. In general, magnesium alloys are more difficult to extrude than aluminum alloys. The extrusion speed commonly used for magnesium alloys is 5–10 times slower than those used for most aluminum alloys, and the extrusion needs to be carried out at a higher pressure or higher temperature, which inevitably increases the processing cost. Together with the higher cost of magnesium billets, extruded magnesium products are more expensive than aluminum products of similar profiles. The extrudability of a specific magnesium alloy is usually assessed by its extrusion limit diagram that specifies the range of speed and temperature over which this alloy can be extruded without any visible surface defects (Atwell and Barnett, 2007). Alloy composition is a crucial factor in controlling extrudability of magnesium alloys. In general, alloys having a lean composition have a larger processing window and therefore can be extruded at much higher speed. Within the extrusion limit diagram, faster extrusion leads to coarser grains and thus lower strength of the extruded product. The most common extrusion alloy is AZ31 (95.7Mg, 3Al, 1Zn, 0.3Mn, wt%). The contents of Al and Zn in this alloy are not sufficiently high for any precipitation hardening. The extrusions of this alloy are used in the as-extruded state. Extrusions of alloy AZ80 (90.88Mg, 8.5Al, 0.5Zn, 0.12Mn, wt%) and ZK60 (94.05Mg, 5.5Zn, 0.45Zr, wt%) are usually used in a T5 temper, and ZK60, WE43 and WE54 extrusions are normally given a T6 temper before their final applications.

Similar to the billets used for magnesium alloy extrusions, slabs for magnesium alloy sheets are produced by direct chill casting, and they need to be homogenized for up to 24 h at 300–500 °C, machined to certain sizes, before being repeatedly hot rolled in the temperature range 300–500 °C. The typical thickness reduction is 10% per pass in order to avoid any cracking of the rolled alloy plate. Intermediate reheats are often used due to the low volumetric heat content of magnesium and the relatively limited process window of hot rolling. Some alloys are also cold rolled, annealed or aged after hot rolling. The rollability of magnesium alloy is influenced by alloy composition and processing parameters such as hot rolling temperature, thickness reduction per pass, and rolling speed. Higher-temperature hot rolling gives rise to better rollability of magnesium alloy plate because of the activation and operation of more deformation modes such as non-basal slip and twinning and accelerated processes of dynamic recrystallization and grain growth. It may also lead to weaker basal texture and thus better stretch formability of the resultant sheet. A higher rolling speed usually leads to better rollability, which is attributable to more deformation modes activated at higher strain rates and the accelerated occurrence of dynamic recrystallization. Increased thickness reduction per pass can also lead to reduced sizes of recrystallized grains and more homogeneous microstructure. The original microstructure in the as-cast or homogenized state is usually fully replaced after repeated deformation and recrystallization. Nowadays, it is possible to commercially produce magnesium alloy sheet with a minimum thickness of 0.35 mm to a width of over 2 m. Most magnesium sheet is made of alloy AZ31 and is generally used in H24 temper which is a hard-rolled state.

Continuous sheet casting

Twin-roll casting (TRC) of magnesium strips emerged in the past two decades as an energy-efficient alternative process for producing magnesium sheet. In the TRC process, molten metal is poured between two large counter-rotating water-cooled rolls and solidifies as a thin shell against each of the two cold rolls. The two solid shells are compressed together at the so-called kissing point of the two rolls and exit as a single strip having a thickness of about 3–5 mm that can be further reduced down to 0.35 mm using a conventional finishing mill. The width of the strip and hence the sheet can be up to 2 m, depending on the size of the rollers. Compared with the conventional route for sheet production, the TRC process significantly reduces the energy and capital costs. A range of magnesium alloys, including AZ31, ZM61 (92.8Mg, 6Zn, 1.2Mn, wt%) and some new alloy compositions, have been successfully twin-roll cast into thin strips. Challenges to wider industry adoption of the TRC process are the tendency of the molten magnesium metal to oxidize during the operation, surface defects and internal segregation. A typical internal defect is centerline segregation that arises from the impingement of the two dendritic solidification fronts, which are enriched in alloying elements, in the center of the strip.

Machining

Magnesium alloys can be readily machined. For the machining of magnesium alloys, the amount of power required is approximately 55% of that for aluminum alloys and 10% of that for stainless steels; the drilling speed is generally about 50% higher than that for aluminum alloys and more than 20 times higher than that for stainless steels; and the rough turning speed is about 1.9 times faster than that for aluminum alloys and 21 times faster for stainless steels. While magnesium alloys can be machined in air, they are usually machined with a coolant such as mineral oils. This is because magnesium swarf or fine turnings may ignite in air and they may also chemically react water-based coolants. Magnesium alloys can also be chemically machined. Some of them are prone to contour etching and AZ31 is used for producing printing plates.

Welding and Joining

Manufactured products made of either cast and wrought magnesium alloys can be welded by inert gas shielded tungsten arc or consumable electrode processes. The to-be-welded products are often preheated to 250–300 °C to reduce weld cracking during solidification. While generally having the same composition as the to-be-welded product, filler rods having higher alloying contents and thus lower melting point and wider freezing range are also used in order to reduce or eliminate hot cracks in the weld. Since magnesium has low heat capacity and heat of fusion, the welding of magnesium products can be done with less energy and higher speed than those for aluminum products. However, the relatively high vapor pressure of molten magnesium can cause some evaporative loss during welding, and the relative low viscosity and low surface tension of liquid magnesium lead to increased sputter during welding and reduced surface quality of the welded region. In recent years, friction stir welding, in which heat is generated through mechanical friction between a rapidly rotating pin and two stationary products to plastically deform and to fuse the two pieces together, has been increasingly used to join products made of either similar or different magnesium alloys, or join magnesium products to products made of other metals such as aluminum alloys or steels. Since liquid phase is not formed in this technique, shielding gas is not required during the welding. Due to the severe plastic deformation involved in the friction stir welding (FSW) process, the weld has a much finer microstructure and thus better mechanical properties than the base alloy. A derived technique named friction stir processing is also increasingly used to modify the surface of magnesium plates and sheets for better mechanical properties and corrosion resistance.

Additive manufacturing

Additive manufacturing, also known as 3D printing, has emerged in recent years as a new technology to build parts of complex internal or external geometries layer by layer from powder or wire of metallic alloys. It offers an opportunity to manufacture components that cannot be made by conventional casting or thermomechanical processing routes. Many additive manufacturing technologies are available, but only selective laser melting, selective electron beam melting and direct metal deposition-based additive manufacturing processes have received more attention and wider industry applications. While a variety of metallic materials have been additively manufactured, including superalloys, stainless steels, and alloys of titanium, aluminum and magnesium, 3D printing of magnesium alloy products is still in its infancy. A key reason is that magnesium alloys are difficult to be additively manufactured. Magnesium alloys have low vaporization temperature, and their powders are highly combustible. Gas-atomized magnesium alloy powders such as Elektron 91, 43 and 21 have been specifically designed and optimized for additive manufacturing. Compared to powder-based additive manufacturing technologies, wire deposition-based processes have lower risk of combustion and a higher production rate, and they appear to be more promising for laboratory and industry production of magnesium parts.

High-pressure die cast magnesium alloys

Magnesium alloys based on the Mg-Al system represent the most widely used high-pressure die cast magnesium alloys. They have been used in automotive vehicles due to their excellent castability and the weight savings they provide. The notable alloy is AZ91, Table 2. The addition of zinc can generate some strengthening effect, but it has to be controlled to be less than 1 wt% over which

Commercial aluminium casting alloy 380 is also included for the purpose of comparison.

causes increased susceptibility to hot cracking during solidification. About 0.3 wt% manganese is also added to this alloy for the purpose of corrosion resistance. AZ91 has excellent die-castability, but its ductility and fracture toughness are moderate presumably because of the eutectic particles or discontinuous precipitates of the equilibrium β phase that has a composition of $\text{Mg}_{17}\text{Al}_{12}$. Alloys containing less aluminum have been developed, including AM60 and AM 50 (94.7Mg, 5Al, 0.3Mn, wt%), so that the amount of $\text{Mg}_{17}\text{Al}_{12}$ phase around grain boundaries is reduced. These aluminum-lean alloys have better ductility and fracture toughness, and they have been used to fabricate automotive parts such as steering wheels, seat frames and wheels.

While the AM series alloys exhibit good strengths at room and elevated temperatures, they are prone to substantial creep deformation when exposed to moderate loads at temperatures above 150 °C. The widely accepted interpretation attributes the inferior creep resistance of the AM series alloys to discontinuous precipitation of the equilibrium $\text{Mg}_{17}\text{Al}_{12}$ phase at grain boundaries or to softening of the $\text{Mg}_{17}\text{Al}_{12}$ phase during creep. In this interpretation, grain boundary sliding is assumed to be the major creep deformation mode and discontinuous precipitation of $\text{Mg}_{17}\text{Al}_{12}$ during creep is the key factor that limits the creep resistance of the AM series alloys. However, the reduced volume fraction of discontinuous precipitates of $\text{Mg}_{17}\text{Al}_{12}$ in AM60 and AM50 alloys leads to only moderate improvement in creep resistance. An alternative interpretation is that the excessive creep deformation of the AM series alloys is primarily due to the relatively high diffusivity, combined with relatively high concentrations, of aluminum in solution in the α -Mg matrix. This interpretation is supported by experimental observations that only limited improvements in creep resistance is obtained in alloys containing significant amounts of Al and yet free of discontinuous precipitation of the $\text{Mg}_{17}\text{Al}_{12}$ phase. According to this interpretation, further improvements in creep resistance of magnesium die casting alloys can be achieved by reducing the equilibrium solid solubility of aluminum in magnesium and/or adding alloying elements that have lower solid diffusivity and are yet soluble in magnesium.

Creep resistance of Mg-Al alloys is improved by adding a small amount of silicon which can reduce the amount of $\text{Mg}_{17}\text{Al}_{12}$. Two commercial alloys, namely AS41 (94.2Mg, 4.5Al, 1Si, 0.3Mn, wt%) and AS21 (96.5Mg, 2.2Al, 1Si, 0.3Mn, wt%), have been developed, Table 2. While alloy AS21 has better creep resistance than AS41, it is more difficult to die cast because of the reduced fluidity resulting from the lower aluminum content in this alloy. During the fast solidification in high-pressure die casting, the silicon combines with some of the magnesium to precipitate fine and relatively hard particles of Mg_2Si in grain boundaries.

The addition of rare-earth (RE) elements to Mg-Al alloys leads to the development of two commercial die-cast alloys, AE42 (93.7Mg, 4Al, 2RE, 0.3Mn, wt%) and AE44 (91.7Mg, 4Al, 4RE, 0.3Mn, wt%) (Bakke et al., 2007), that have superior creep resistance to the AS41 and AS21 alloys, Table 2. The alloy AE42 was developed first, but its creep properties deteriorate rapidly at temperatures higher than 175 °C, presumably because of the relatively high level of aluminum retained in the α -Mg matrix after die casting. The creep properties of this alloy are improved by adding more rare-earth elements, which led to the development of alloy AE44, which was intended for automotive powertrain applications where the operating temperature may go up to 200 °C. The improved creep resistance is attributed to increased content of RE-containing intermetallic phases and reduced aluminum content in the α -Mg matrix resulting from increased RE content. The addition of different RE elements leads to different intermetallic phases in the microstructure, but it does not strongly affect the creep resistance of die-cast AE44 alloys. It is for this reason that a lower-cost variant of the AE44 alloys, which uses cheaper RE element lanthanum, has received more research and attention. The dominant intermetallic phase is (Al, Mg)₃La in the die-cast Mg-4Al-4La (92Mg, 4Al, 4La, wt.%) alloy, and $\text{Al}_{11}\text{RE}_3$ in the die-cast Mg-4Al-4Ce (92Mg, 4Al, 4Ce, wt%) alloy. The (Al, Mg)₃La and $\text{Al}_{11}\text{RE}_3$ phases are thermally stable at temperatures up to 500 °C, and they are likely to be the equilibrium phase in their alloys. Each of these two phases forms as fine-scale lamellae in inter-dendritic regions of magnesium grains. The addition of a small amount (0.3 wt%) of manganese to die-cast alloy AE44 leads to remarkable enhancement in creep resistance. The improved creep resistance is due to dynamic precipitation of nano-scale Al-Mn particles during creep that reduces dislocation slip. Indeed, the manganese-containing AE44 alloys exhibit moderate age hardening response when they are isothermally aged at 200–300 °C after die casting. These alloys can be aged by a T5 temper without any ductility loss, as demonstrated (Zhu et al., 2021).

The addition of alkaline earth elements such as strontium and/or calcium to Mg-Al alloys leads to substantial enhancement in creep properties, Table 2. Both strontium and calcium have some adverse effect on alloy castability and increase the susceptibility to hot tearing, therefore they are usually added to alloys containing higher aluminum contents. Sr or Ca additions reduce the equilibrium solid solubility of Al in α -Mg grains, and the solid solution of Ca or Sr, which have a larger atomic size than Mg, in α -Mg can also reduce the overall diffusion rate of atoms in the alloy. The precise role of Sr and Ca in improving the creep resistance is still unclear due to the lack of data on the diffusivity of Ca in solid magnesium and detailed understanding of microstructures of these alloys. A few experimental alloys have been developed and found industrial applications (Pekguleriyuz and Kaya, 2003), including AJ62 (91.7Mg, 6Al, 2.3Sr, wt%), AXE522 (91Mg, 5Al, 2Ca, 2RE, wt%), AX81 (91Mg, 8Al, 1Ca, wt%), and those that are known only by their proprietary designations such as MRI153M (90.7Mg, 8Al, 1Ca, 0.3Sr, wt%), and MRI230D (90.2Mg, 6.5Al, 2Ca, 1Sn, 0.3Sr, wt%). The alloy AJ62 has been used to die-cast around an aluminum alloy core to make a hybrid 6-cylinder engine for one model of BMW cars. Although substantial improvements in creep resistance are obtained in die-cast alloy AJ62 that does not have any precipitates of $\text{Mg}_{17}\text{Al}_{12}$, the creep resistance of this alloy is still significantly inferior to those of sand cast magnesium alloys based on the Mg-RE systems.

Mg-RE based alloys have been developed for high-pressure die casting and for elevated temperature applications. An alloy developed in early days is MEZ (96.65Mg, 2.5RE, 0.5Zn, 0.35Mn, wt%). It has better creep resistance than die-cast AE42 at temperatures above 150 °C, but its tensile yield strength and ductility at room temperature are both low. Subsequently, a modified version that contains a larger amount of RE elements in different combinations was developed to address the inferior strength at room temperature. This alloy, designated EZ41 (95.83Mg, 1.63La, 0.97Ce, 0.96Nd, 0.11Y, 0.5Zn, wt%) and also known as AM-HP2, exhibits excellent creep resistance at temperatures 150–200 °C (Zhu et al., 2015).

Sand cast or permanent mold cast magnesium alloys

One of the key requirements for the alloying elements used in sand casting magnesium alloys is that their equilibrium solid solubility in magnesium decreases with temperature so that the resultant alloy is age hardenable. While the solid solubility of aluminum in magnesium decreases from a maximum of 12.7 wt% at 437 °C to around 2% at room temperature, the decomposition of the supersaturated solid solution of alloy AZ91 does not lead to any significant precipitation hardening. This is due to the absence of GP zones and intermediate precipitate phases. The equilibrium precipitate β forms directly from the supersaturated solid solution upon artificial ageing, in the form of continuous precipitates inside individual magnesium grains and discontinuous precipitates along grain boundaries. The coarse distribution of this precipitate phase is unable to generate any sufficient age hardening. Additions of trace elements to this alloy do not seem to be effective in refining the distribution of the β precipitate.

Adding larger amount of zinc to Mg-Al alloys leads to the development of Mg-Zn-Al alloys with the Zn:Al weight ratio in the range 3:1 to 1:1. Examples include Mg-12Zn-4Al (84Mg, 12Zn, 4Al, wt%), Mg-8Zn-8Al (84Mg, 8Zn, 8Al, wt%) and Mg-8Zn-4Al (88Mg, 8Zn, 4Al, wt%) alloys. Some of these alloys are also suitable for high-pressure die casting due to their excellent castability. These alloys contain large volume fractions of intermetallic particles of equilibrium ϕ phase and/or metastable icosahedral quasi-crystalline i phase. A fraction of these particles can be dissolved after heat treatment at temperatures close to 325 °C. When the alloy is water quenched after this relatively high temperature heat treatment, an appreciable level of supersaturation of Zn and Al atoms in magnesium can be obtained. Subsequent ageing at 150–200 °C leads to a remarkable age hardening response, which is due to the formation of a finely dispersed, diamond-shaped precipitates having a quasi-crystalline structure. Quaternary addition of a small amount of Ca to the Mg-Zn-Al alloy does not change the age hardening response, but it leads to an enhancement in creep resistance.

Most alloys based on the Mg-Zn system are age hardenable. Binary Mg-Zn alloys can be grain refined by zirconium, and two commercial alloys, ZK51 (94.8Mg, 4.5Zn, 0.7Zr, wt%) and higher strength ZK61 (93.3Mg, 6Zn, 0.7Zr, wt%) have been developed. However, these two alloys have reduced age hardening response, and they are susceptible to microporosity, prone to hot cracking, and not weldable. For this reason, the commercial use of these alloys is very limited. The addition of 3 wt% copper to binary Mg-6Zn (94Mg, 6Zn, wt%) alloy reduces the susceptibility of the binary alloy to microporosity and eliminates the tendency to hot cracking. In addition, the addition of copper to the binary Mg-Zn alloy raises the eutectic temperature and allows higher temperatures to be used for solution treatment so that higher concentrations of zinc and copper in solid solution can be obtained for stronger age hardening response. The resultant alloy ZC63 (90.5Mg, 6Zn, 3Cu, 0.5Mn, wt%) has been commercially produced by sand casting (Westengen and Aune, 2006), and the castings can be welded using the standard tungsten-inert gas technique. However, this alloy has not found applications in the automotive industry because of the corrosion problem. The most successful commercial alloy in this group of alloys is ZE41 (93.9Mg, 4.2Zn, 1.3Ce, 0.6Zr, wt%). In T5 temper condition, this alloy has moderate strength at temperatures up to 150 °C and has been used to cast transmission housings of helicopters.

Rare earth (RE) elements such as Nd, Y, and Gd have relatively large solid solubility in magnesium. They are effective in solid solution strengthening and resultant alloys respond well to age hardening even at relatively high ageing temperatures. A commercial alloy that has been developed based on the Mg-Y-Nd-Zr system is WE54 (Westengen and Aune, 2006). Since pure yttrium is expensive, difficult to alloy with magnesium and has strong affinity for oxygen, a cheaper yttrium-rich misch-metal containing around 75% of yttrium, together with heavy rare earth metals such as gadolinium and erbium, has been used for yttrium. The alloy WE54 has high strength at ambient and elevated temperatures and superior creep resistance at temperatures up to 300 °C, Table 3. In addition, its corrosion resistance is superior to that of other high-temperature magnesium casting alloys, and comparable with aluminum casting alloys A356 and A357. The strength of this alloy is achieved via precipitation of plate-shaped precipitates formed on prismatic planes of magnesium. The shape and orientation of such precipitates are quite effective in impeding dislocation glide and propagation of deformation twins. Precipitation process in this alloy is complex, and it involves the formation of short-range ordered solute clusters, GP zones and several intermediate precipitate phases (Nie et al., 2016).

The alloy WE54 is typically produced by sand casting and used in T6 temper. However, subsequent practical applications of this alloy indicated that the ductility of this alloy gradually decreased to unacceptable levels during prolonged exposure to temperatures around 150 °C. This reduction in ductility is due to secondary precipitation of GP zones that occurs slowly throughout the grains. Subsequently, an alternative composition WE43 was developed. The slightly reduced yttrium content and the slightly increased neodymium content in this alloy permits the originally adequate ductility to be retained during long-term exposure at elevated temperatures. Alloy WE43 is being used to sand cast transmission housings for helicopters and some components for racing car engines. Some Mg-Gd-Y-Zr experimental alloys that have superior strength to the WE alloys have been developed in recent years. These alloys contain larger amount of RE elements, typically in the range 10–16 wt%. Gadolinium is used in these alloys because its solid solubility in magnesium is several times higher than that of neodymium at the solution treatment temperature, therefore it is added in larger quantity to obtain larger volume fraction of precipitates. The Mg-Gd-Y-Zr alloys have stronger age hardening response than the WE alloys when they are aged at 200–250 °C. The precipitates formed in these alloys are similar to those observed in the WE alloys.

WE alloys and the Mg-Gd-Y-Zr alloys are expensive and thus they are only used for aerospace applications. Requirements for a cost-effective Mg-RE alloy for automotive cylinder blocks and crank cases led to the development of an alloy designated EZ30 (96.5Mg, 2.7RE, 0.3Zn, 0.5Zr, wt%, also known as AM-SC1 (Bettles et al., 2003)). The RE content in this alloy is much lower than those in the WE alloys and the Mg-Gd-Y-Zr alloys, but the dominant use of Nd and Ce led to sufficient age hardening response and thus strength. In a T6 temper, its overall mechanical properties such as tensile and compressive strengths, creep resistance and

Table 3 Mechanical and physical properties of commonly used sand cast or permanent mold cast magnesium alloys.

fatigue, and corrosion properties all meet the requirements for automotive engine blocks. A sand cast 3-cylinder diesel engine made of this alloy, weighs about 14 kg, and was road tested over 40,000 km in a Volkswagen Lupo car. The addition of a small amount of gadolinium to a Mg-Nd-Zn-Zr alloy led to the development of a proprietary alloy designated EV31 (95.1Mg, 3Nd, 1Gd, 0.4Zn, 0.5Zr, wt%, also known as Elektron 21). This alloy has mechanical and corrosion properties similar to WE43, and improved strength and creep resistance over the EZ30 alloy.

Mg-Gd alloys containing a few weight percent of gadolinium do not exhibit age hardening response when they are aged at 200–250 °C. The addition of small amount of zinc, silver, or in combination to Mg-Gd alloys can generate a significant age hardening response and an improved creep resistance. This remarkably improved tensile and creep strengths is due to the formation of a uniform and dense distribution of nano-scale precipitates that is absent in the Mg-6Gd-0.6Zr (93.4Mg, 6Gd, 0.6Zr, wt%) alloy. For example, the Mg-6Gd-2Ag-0.6Zr (91.4Mg, 6Gd, 2Ag, 0.6Zr, wt%) alloy exhibits the highest hardness increment during isothermal ageing at 200 °C (Gao and Nie, 2008). An increase in the Gd content led to the development of an experimental alloy, Mg-15Gd-2Ag-0.6Zr (82.4Mg, 15Gd, 2Ag, 0.6Zr, wt%) alloy, that has a 0.2% proof strength of 320 MPa when tested in a T6 temper at room temperature, which is the highest among the magnesium casting alloys (Nie, 2012). The Mg-6Gd-2Zn-0.6Zr (91.4Mg, 6Gd, 2Zn, 0.6Zr, wt%) alloy in a T6 temper has a tensile strength of 137 MPa at 25 °C and 124 MPa at 175 °C. Its creep resistance (stress to produce 0.1% strain at 100 h) is well above 90 MPa at 175 °C (Nie et al., 2005). The most notable commercial alloy in the silver-containing magnesium casting alloys is QE22 (94.8Mg, 2.5Ag, 2RE(Nd), 0.7Zr, wt%). The precipitation process in this alloy has not been well studied, even though the maximum age hardening response and the excellent creep resistance are associated with the presence of thermally stable nano-scale precipitates in the microstructure. Alloy QE22 has superior tensile properties at temperatures up to 250 °C and creep resistant up to 200 °C. This alloy has been used for sand casting aerospace components such as helicopter rotor fittings, gearbox housings and aircraft landing wheels.

Magnesium extrusion alloys

Mg-Al based alloys

Alloy AZ31 is commonly used for extruding solid and hollow profiles for general purpose applications. Depending on the extrusion profile and extrusion conditions, the extrusions of this alloy may have quite different textures. Cylindrical solid bars of this alloy extruded at temperatures below 400 °C and a relatively low speed usually have a strong basal texture, with basal planes and $\langle 10\bar{1}0 \rangle$ directions of most grains lying nearly parallel to the extrusion direction (ED). The removal of Zn from this alloy does not change the texture. In general, an increase in extrusion temperature or extrusion speed causes more grains to have their $\langle 2\bar{1}10 \rangle$ axes lying nearly parallel to the ED, in addition to the dominant presence of the $\langle 10\bar{1}0 \rangle \sim //$ ED texture. Extrusions made at temperatures above 450 °C generally have a dominant $\langle 2\bar{1}10 \rangle \sim //$ ED texture. These textures can all be classified as basal fibre textures (BF-1 and BF-2 in Fig. 4) (Nie et al., 2020). The $\langle 10\bar{1}0 \rangle \sim //$ ED (BF-1) is commonly termed deformation texture, which is also seen in warm or cold extruded products of pure magnesium, Mg-Al, Mg-Mn, Mg-Li and Mg-RE alloys, and $\langle 2\bar{1}10 \rangle \sim //$ ED (BF-2) is termed the recrystallisation texture.

Alloy AZ31 produced under commonly used extrusion conditions usually suffers from a problem of tension-compression yield asymmetry; its yield strength under compression is much lower than that under tension, Table 4. This problem is intimately related to the strong basal texture of the extrusion. The basal texture allows $\{10\bar{1}2\}$ deformation twins to form readily upon compressive

Fig. 4 Extrusion textures of magnesium and its alloys. Adapted from Nie JF, Shin KS, Zeng ZR (2020) Microstructure, deformation, and property of wrought magnesium alloys. *Metallurgical and Materials Transactions A: Physical Metallurgy and Materials Science* **51**: 6045–6109.

loading along the extrusion direction—leading to occurrence of plastic deformation at lower stress. Decreasing extrusion temperature can reduce the tension-compression yield asymmetry problem. Extrusions made at temperatures around or below 175 °C have comparable tensile and compressive yield strengths, and the tension-compression yield asymmetry problem is thus fully eliminated due to the significantly reduced grain size, which makes deformation twinning difficult to occur upon compressive loading. Extrusions of ultra-high strength have been made based on a Mg-3.5Al-3.3Ca-0.4Mn (92.8Mg, 3.5Al, 3.3Ca, 0.4Mn, wt%) alloy that is extruded at 350 °C with a relatively low speed. They have a tensile strength of 410 MPa and a ductility of 5.6% when tested at room temperature. Their microstructure has a predominant $\langle 10\bar{1}0 \rangle$ // ED texture, and it contains a mixed distribution of dynamic recrystallized grains of $\sim 1 \mu\text{m}$, elongated strips of deformed grains, intermetallic particles of $\sim 0.5 \mu\text{m}$, and nano-scale precipitates. Dilute alloys based on the Mg-Al-Ca-Mn system have also been experimentally developed for higher speed extrusion and thus lower processing cost. One example is a Mg-0.3Al-0.21Ca-0.47Mn (99.02Mg, 0.3Al, 0.21Ca, 0.47Mn, wt%) alloy that can be extruded at 500 °C with a remarkable speed of 60 m min⁻¹ without any surface defects (Nakata et al., 2018). The as-extruded microstructure has fully recrystallized grains of $\sim 27 \mu\text{m}$ and a weakened basal texture. This alloy is also age hardenable. When tested in a T5 temper, the fast extruded products of this alloy have a tensile yield strength of 207 MPa and a ductility to 13%.

Mg-Zn based alloys

Most alloys based on the Mg-Zn system are age hardenable and suffer less from the problem of tension-compression yield asymmetry, especially when the alloy has a higher alloying content and is in a T6 temper. The commercial alloys developed thus far include ZM21 (97Mg, 2Zn, 1Mn, wt%), ZK30 (96.55Mg, 3Zn, 0.45Zr, wt%), ZK60, ZM61 and ZMC711 (91Mg, 7Zn, 1Mn, 1Cu, wt%). The alloy ZM21 can be extruded at higher speeds. The as-extruded microstructure generally has a mixture of fine-scale equiaxed recrystallized grains and coarse elongated un-recrystallized grains. The size and area fraction of recrystallized grains increase with increased extrusion speed or temperature, which leads to decreased yield strength and increased elongation. A laboratory alloy developed in recent years is ZE20 (97.8Mg, 2Zn, 0.2Ce, wt%). This alloy can be extruded at a speed 25% higher than AZ31 for extrusions at 400 °C, and the extrusions have a tensile yield strength of 135 MPa and a ductility of 27% that are better than those of AZ31. An increase in the zinc content in Mg-Zn based alloys causes deterioration in extrudability. This undesirable effect is reduced by adding zirconium. Alloy ZK60 can be extruded at a speed that is an order of magnitude higher than that of Mg-6Zn (94Mg, 6Zn, wt%) alloy. This enhanced extrudability is due to the fine and uniform as-cast grain size of the billet and the increased solidus temperature of the alloy ZK60. Extrusions of alloy ZK60 respond well to age hardening and hence they are commonly used in a T5 temper. Extruded bars of ZM61 may exhibit a tensile yield strength of 340 MPa and a ductility of 8% when tested in a T6 temper. Alloy ZMC711 was developed as a weldable high strength extrusion alloy but finds little application nowadays due to its corrosion problem.

Mg-Mn-RE based alloys

A few Mg-Mn based alloys have been developed for higher speed extrusion. Binary Mg-1Mn (99Mg, 1Mn, wt%) alloy has extrudability superior to other magnesium extrusion alloys and its processing window is as large as that of wrought aluminum alloy AA6063. The addition of 0.4 wt% cerium-rich mischmetal to this alloy led to a commercial alloy designated ME10 (also known as AM-EX1 (Easton et al., 2008)). This alloy can be extruded at a speed two times faster than AZ31, and its tensile yield strength is compatible with those of AZ31 and T6 tempered AA6063. It also has better ductility and reduced tension-compression asymmetry, due to the finer grain size and the presence of pyramidal (non-basal) fiber texture (Fig. 4).

Mg-RE based alloys

Several commercial and experimental alloys have been developed based on the Mg-RE system, including WE54, WE43, EV31 and VW76 (86.5Mg, 7Gd, 6Y, 0.5Zr, wt%; also known as Elektron 675). These alloys all contain large amount of RE elements and hence they have to be extruded at very low speeds at higher temperatures. These alloys do not suffer from the problem of tension-compression yield asymmetry, and their tensile properties are also quite uniform when tested along the directions parallel and perpendicular to the extrusion direction. Due to the high cost of RE elements and processing, these alloys are mainly used for defense and specialized applications. A unique feature of extrusions of these alloys is the combination of high tensile strength and good creep resistance at elevated temperatures. Alloy VW76 has the highest elevated temperature tensile yield strength, in addition to its good fatigue strength and excellent resistance to corrosion and ignition. For example, extrusions of this alloy have 310 MPa tensile yield strength and 9% ductility when tested a T6 temper and at room temperature, and their tensile yield strength is still above 300 MPa when the testing temperature reaches 200 °C. Further increase in the RE and Zn contents led to the development of a remarkably stronger laboratory alloy VWZ1062 (82Mg, 10Gd, 5.7Y, 1.6Zn, 0.7Zr, wt%). In a T5 temper, extrusions of this alloy have 473 MPa tensile yield strength and 8% ductility, 524 MPa compressive yield strength and 6% plasticity. The T5 treatment generates a dense distribution of nano-scale precipitates inside magnesium grains, and hence an enhancement in strength. The presence of the precipitates and the small grain size suppress the activation of deformation twinning upon compressive loading, hence the tension-compression asymmetry is eliminated.

Extrusions of Mg-RE based alloys exhibit more and unique textures. The microstructure of WE43 alloy has a mixture of $\langle 10\bar{1}0 \rangle // ED$ and $\langle 2\bar{1}\bar{1}1 \rangle // ED$ textures in the as-extruded condition, but a dominant $\langle 2\bar{1}\bar{1}1 \rangle // ED$ texture in the fully-annealed condition. The $\langle 2\bar{1}\bar{1}1 \rangle // ED$ is a pyramidal fiber texture (Fig. 4) also known as RE-texture. It is also commonly observed in extrusions of magnesium alloys containing dilute RE contents (as low as 0.5–1.0 wt%) and some RE-free alloys such as Mg-Zn-Ca-Mn. Other pyramidal-fiber textures are also frequently observed in extruded Mg-RE alloys, including pyramidal plane//ED and $\langle 10\bar{1}m \rangle // ED$ (PyF-1), pyramidal plane//ED and $\langle 2\bar{1}\bar{1}n \rangle // ED$ (PyF-2), or pyramidal plane//ED and $\langle 2\bar{1}\bar{1}n \rangle - \langle 10\bar{1}m \rangle // ED$, where m represents 2/3, 1, or 1.5, and n represents 1, 2, or 3. In addition, a prismatic texture in the form of prismatic plane//ED and $[0001] // ED$ (PrF, Fig. 4) is also found in a few alloys that are extruded under some particular conditions. Such alloys include Mg-Mn-RE, Elektron 675, Mg-RE-Zn and Mg-RE-Ag that contain higher amount of RE elements.

Magnesium plate/sheet alloys

Mg-Al based alloys

AZ31 is the most commonly used alloy for fabricating sheet for applications at room or slightly higher temperatures. Sheet of this alloy is strengthened mainly by strain hardening and it is weldable. Hot rolled sheet of AZ31 has a strong basal texture, with a preferred orientation of basal planes parallel to the sheet surface (SB-1 and SB-2 in Fig. 5). The strong basal texture causes unsatisfactory formability at or close to room temperature. Forming limit curves for annealed sheet of AZ31, together with that of aluminum alloy 5052 for the purpose of comparison, are shown in Fig. 6. The formability of AZ31 sheet is adequate when tested at 200 °C, but very poor at room temperature. The formability of AZ31 sheet can be improved by higher temperature hot rolling, reverse rolling (reversing the sheet direction after each rolling pass) or cross rolling.

Mg-Zn based alloys

Several Mg-Zn based sheet alloys have been commercially developed, including ZK31 (96.3Mg, 3Zn, 0.7Zr, wt%), ZM21, ZE10 (98.6Mg, 1.2Zn, 0.2RE, wt%), and ZEK100 (98.4Mg-1.4Zn-0.1RE-0.1Zr, wt%). ZK31 has limited weldability. While ZM21 sheet is weldable and does not require stress-relieving, it has a strong basal texture and hence its formability at room temperature is quite limited. Sheets of ZE10 and ZEK100 are weldable and formable. The addition of small amounts of RE elements to Mg-Zn alloys remarkably weakens the basal texture, with basal poles spreading along the sheet transverse direction (TD), as shown in WB-2 in Fig. 5, and thus improves sheet formability. Forming limit curves of annealed ZE10 sheet is shown in Fig. 6 (Polmear et al., 2017). The ZE10 sheet has better formability than AZ31 at both room temperature and 200 °C under conditions of plane strain and biaxial stretching. It also has better deep drawability than AZ31, but it has greater susceptibility to earing than AZ31. Similar to other magnesium alloy sheets, sheets of ZE10 and ZEK100 suffer from anisotropy of their mechanical properties. Different tensile properties are obtained when the sheet is tested along different directions such as rolling direction (RD), transverse direction (TD) and at 45 degrees to the RD (Al-Samman and Li, 2011), Table 5. Sheet anisotropy is strongly influenced by the type of RE additions and hence the intensity of the weakened basal texture. When tested along the TD, the highest ductility is achieved in the gadolinium-containing sheet, which has weaker basal texture than those in the sheets of alloys containing light RE elements such as cerium, lanthanum, neodymium or misch-metal.

Mg-RE based alloys

Commercial sheets made of Mg-RE based alloys are very limited. Magnesium alloys containing relatively high RE content are generally difficult to roll into thin sheet. Alloy WE43 can be hot rolled into plates and T5 tempered. Such plate may have a fully recrystallized microstructure that has a weakened basal texture. It generally does not have the tension-compression yield asymmetry problem along the rolling, normal and transverse directions of the plate. Reducing the RE content to 1–3 wt% and adding small

amount of zinc led to the development of laboratory alloys VZ21 (97.21Mg, 1.68Gd, 1.11Zn, wt%) and VZ31 (96.2Mg-2.74Gd-1.06Zn, wt%) that can be hot rolled readily into thin sheet (Wu et al., 2011). In the annealed condition, the resultant sheet contains recrystallized grains with a significantly weakened basal texture. It has an excellent stretch formability, together with good tensile yield strength and ductility, when tested at room temperature.

Mg-Li based alloys

Lithium has an ultra-low density (0.53 g cm^{-3}) and substantially large solubility in solid magnesium. Adding more than 5.7 wt% Li to magnesium leads to the formation of a body-centered cubic β -phase, which is essentially a solid solution of magnesium in lithium. The microstructure becomes fully occupied by the β -phase when the lithium content is greater than 11 wt%. These unique features develop Mg-Li alloy sheet or plate that has extensive cold-formability and is attractive for some specific applications where weight-saving is critical. Commercial alloys developed so far include LA141 (85Mg, 14Li, 1Al, wt%), MA18 (85.95Mg, 10.8Li, 2.25Zn, 0.75Al, 0.25Ce, wt%), and MA21 (80.37Mg, 8.75Li, 4.8Al, 4.5Cd, 1.5Zn, 0.08Ce, wt%). All three alloys are weldable. The LA141 alloy has been used for fabricating armor plate and for aerospace components.

Applications of magnesium alloys

Magnesium alloys have been used in a broad range of applications, including automotive vehicles, military aircraft, electronic devices, biodegradable implants, superconductors, shape memory devices, and hydrogen storage. Massive use of magnesium alloys in the automotive industry began in 1930s when Volkswagen started to replace cast iron by magnesium alloys for engine crank case and transmission housing castings in the Beetle motor car, with a weight saving of about 50 kg. Large increases in magnesium price in the mid-1970s led to replacement of such magnesium products by aluminum alloy castings. Driven by environmental legislations and fuel consumption minimization, magnesium products received renewed application in the automotive industry in the first decade of 2000. Current applications of magnesium alloy components include steering wheels and steering column components, instrument panels, seat frames, small motor housings, engine valve cover and oil pan. Developments have also been made with die cast gearbox sand cast engine blocks, which can lead to further significant weight savings. Porsche has recently selected magnesium sheet for the roof of its new model of the 911 GT3. Renault Samsung Motors also decided in recently years to use magnesium sheet for the walls of VIP back seats and the trunks of upgraded SM7 vehicles.

Magnesium alloy castings have been used for engine and transmission housings of helicopters for many years. However, their use in passenger aircraft interiors is still limited due to flammability restrictions imposed by the US Federal Aviation Administration (FAA). FAA announced in 2013 that it would now allow magnesium in aircraft seats provided magnesium alloys are tested to and meet the flammability performance requirements in the FAA Fire Safety Branch document. Currently, WE43 and EV31 are the only two alloys that have passed extensive flammability tests conducted by the FAA, and WE43 is being used to produce 16G-compatible seats which will bring a significant weight reduction compared to commonly used aluminum alloys.

In the past two decades, magnesium alloy die castings have been widely used for thin-wall computer housings, mobile phone and video camera housings where lightness, surface finish and electromagnetic shielding are attractive consideration to customers. Magnesium alloys have also been increasingly used to manufacture frames and wheels of bicycles where light weight and vibration damping capacity are special considerations. In recent years, Magnesium Elektron Limited and BIOTRONIK developed the world's first clinically proven magnesium-based bioresorbable scaffold, SynerMag[®] 410 alloy system. The latest generation BIOTRONIK magnesium scaffold has been clinically trialed. Magnesium alloy MgB_2 was discovered in 2001 (Nagamatsu et al., 2001) to have superconductivity at approximately 40 K (-233°C), which is nearly twice that of the traditional metallic superconductor Nb_3Sn . One very recent discovery is that polycrystalline Mg-Sc alloys containing more than 18 at % (29 wt%) scandium exhibit an interesting shape memory phenomenon (Ogawa et al., 2016). The density of these Mg-Sc alloys is only one-third of those of commonly used TiNi shape memory alloys.

Driven by demands for clean and renewable energies, there has been an increasing interest in developing magnesium-based alloys for solid-state hydrogen storage. Magnesium has an attractively large hydrogen storage capacity. It can store approximately 7.6 wt% hydrogen, more than any other metal or metallic alloy (Shang et al., 2021). However, the hydrides formed in magnesium are very stable, and it is necessary to use a relatively high temperature, $\sim 280^\circ\text{C}$, to release the hydrogen. The kinetic of the hydrogen absorption/desorption process is also slow. It is often necessary to use catalyst to accelerate the reaction. New alloy compositions and dopants and novel processes are currently being extensively explored to solve these problems.

Key issues

There are several issues that restrict wider applications of magnesium alloys. They include price, lack of alloying and manufacturing technologies that can lead to lower-cost and better-performing magnesium products. The magnesium price was about US\$2300 per ton for the past 10 years but jumped over US\$11000 per ton in September 2021, with an average of US\$4700 per ton for the past 12 months. This high price, if sustained, would impose a large barrier to the more usage of magnesium for applications in transportation and electronic industries. In comparison to other commodity materials such as aluminum, the production and processing costs of magnesium products are relatively high, and there remain limited choices in the selection of magnesium alloys for specific applications. The critical technological issues include the lack of effective and low-cost grain refiners for

aluminum-containing magnesium alloys, stronger precipitation hardening alloys for sand castings and wrought products, wrought alloys with higher formability that can lead to lower-processing cost, more corrosion-resistant or stainless alloys. Inevitably, further improvement in existing, or development of new, alloying and/or processing technologies requires better understanding of the complex processing-microstructure-property relationships, which in turn requires deeper understanding of some fundamental issues such as interactions between lattice defects of dislocations and deformation twins and solutes, solute clusters and second-phase particles and their impacts on mechanical properties and formability, the physical origin of the pyramidal-fiber texture in some magnesium extrusions can give rise to less tension-compression yield asymmetry, and whether dynamic recrystallization can be facilitated to occur massively, by adding some specific alloying elements or reducing magnesium grain to below some critical sizes, during room temperature sheet forming. One more recent progress in addressing some of these issues is the development of some compositionally lean magnesium alloys that are intrinsically suitable for higher-speed extrusion or rolling and hence lower processing cost. A strategy used in strengthening such relatively soft alloys is further refinement in magnesium grain size and introduction of nano-scale precipitates that are more effective in strengthening even at a substantially low volume fraction.

Conclusion

Magnesium is abundant and the lightest structural metal. Together with some attractive physical properties such as low melting point and high specific heat, magnesium and its alloys have received increasing attention, more extensive research and wider engineering applications in the past 20 years, especially for energy efficient and environmentally friendly applications in the transportation industry. The magnesium metal annual production has been increased by nearly three times since 2000. Majority of this production is made by the Pidgeon process. Currently, about 45% of the annually produced magnesium metal is used for making magnesium casting alloys, only a tiny fraction ($\sim 5\%$) is used for fabricating wrought products, in contrast to more extensively used steels and aluminum alloys where wrought products dominate. Magnesium itself is not strong enough for engineering applications. It deforms readily by dislocation slip and/or mechanical twinning. Additions of some specific alloying elements can impede or facilitate the deformation modes for better mechanical properties or formability. There are more commercial magnesium casting alloys than wrought alloys, even after extensive global research on wrought alloys in the past 20 years. Magnesium products are usually produced from magnesium alloys by high-pressure die casting, permanent mold casting or sand casting or thermomechanical processing such as hot extrusion or hot rolling. These manufactured products can be readily welded by conventional welding technologies. While a remarkable progress has been made in the development and application of magnesium alloys, the full potential of magnesium alloys, as an emerged class of materials for engineering, energy or biomedical applications, is still far from being fully explored. There remain some critical scientific and technological issues that require better understanding at fundamental and experimental levels. With the advent of new manufacturing and processing technologies, advanced facilities for microstructural characterization, and super-computing facilities for atomistic understanding of impacts of solute atoms of added alloying elements, it is foreseeable that properties and applications of magnesium alloys can be further enhanced and widened to the level currently enjoyed by aluminum alloys.

Abstract

The most commonly used methods for treating the impurity and defect states in metals and alloys start with the calculation of the one-electron Green's function $G(E, \mathbf{r}, \mathbf{r}')$ (Faulkner and Stocks, 2019). The density functional theory (DFT) makes it possible to write a simple equation for this function. The local density approximation or the generalized gradient approximation are used to generate the effective one-electron potential $V(\mathbf{r})$. In any version of the DFT, $V(\mathbf{r})$ is a functional of the density of the electrons in the system, $\rho(\mathbf{r})$, which means that the one-electron equation must be solved self-consistently.

Introduction

The most commonly used methods for treating the impurity and defect states in metals and alloys start with the calculation of the one-electron Green's function $G(E, \mathbf{r}, \mathbf{r}')$ (Faulkner and Stocks, 2019). The density functional theory (DFT) makes it possible to write a simple equation for this function

$$\left[E + \frac{\hbar^2}{2m} \nabla^2 - V(\mathbf{r}) \right] G(E, \mathbf{r}, \mathbf{r}') = \delta(\mathbf{r} - \mathbf{r}') \quad (1)$$

The local density approximation or the generalized gradient approximation are used to generate the effective one-electron potential $V(\mathbf{r})$. In any version of the DFT, $V(\mathbf{r})$ is a functional of the density of the electrons in the system, $\rho(\mathbf{r})$, which means that the one-electron equation must be solved self-consistently. The charge density is obtained from the Green's function by integration

$$\rho(\mathbf{r}) = -\frac{2}{\pi} \int_{-\infty}^{E_F} G(E, \mathbf{r}, \mathbf{r}) dE, \quad (2)$$

where the Fermi energy E_F is defined by the requirement that the integral of $\rho(\mathbf{r})$ over all space is equal to the total number of electrons, and the 2 is required by the electron spins. The total energy is

$$E_{total} = \sum_{occ} E_i - \frac{1}{2} \int \frac{\rho(\mathbf{r})\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}d\mathbf{r}' + E_{xc}[\rho] - \int \frac{\delta E_{xc}[\rho]}{\delta \rho(\mathbf{r})} \rho(\mathbf{r}) d\mathbf{r}. \quad (3)$$

The sums are over all occupied states including spin, and the exchange correlation functional $E_{xc}[\rho]$ is determined by the particular method used to calculate the effective one-electron potential.

The one-electron potential for a metal or alloy can be written as a sum of potentials that describe the interaction of the electron with each of the atoms in the solid

$$V(\mathbf{r}) = \sum_{i=1}^N v_i(\mathbf{r} - \mathbf{R}_i). \quad (4)$$

In order to eliminate surface states, it is convenient to imagine the N atoms in the solid are in a supercell, and that the supercells are periodically reproduced to fill all space. The potential associated with the i th atom with its nucleus at $\mathbf{R}_i$, $v_i(\mathbf{r} - \mathbf{R}_i)$, is zero outside of

the region Ω_i . The Ω_i fill the entire supercell and do not overlap. At some point, N will be allowed to approach infinity and the supercell to fill all space.

The Green's function from multiple scattering theory

The multiple scattering equations for wave functions are derived and discussed in the article Electronic Structure: Scattering methods (for electronic structure calculations). The version of these equations that deals with Green's functions starts from the operator equation (Faulkner and Stocks, 1980).

$$G(z) = (z - H_0 - V)^{-1} = G_0(z)[I + VG(z)] = G_0(z) + G_0(z)T(z)G_0(z), \quad (5)$$

where H_0 is the kinetic energy operator, z is a complex energy, and

$$G_0(z) = (z - H_0)^{-1}. \quad (6)$$

For the case that the potential is a sum of atomic potentials as in Eq. (4), the scattering matrix for the system,

$$T(z) = V[I + G_0(z)T(z)] \quad (7)$$

can be written

$$T = \sum_{i=1}^N \sum_{j=1}^N \tau^{ij}, \quad (8)$$

where the scattering path operator τ^{ij} is

$$\tau^{ij} = t^i \delta_{ij} + t^i G_0 \sum_{k \neq i}^N \tau^{kj}, \quad (9)$$

and $t^i = (1 - v_i G_0)^{-1} v_i$ is the t-matrix that describes the scattering from $v_i(\mathbf{r} - \mathbf{R}_i)$ embedded in a vacuum.

A function that is very useful in analyzing experiments is the density-of-states (DOS) $\rho(E)$, which is the number of energy levels between the energies E and $E + dE$. The DOS associated with just the i th atom can be calculated from,

$$\rho_i(E) = -\frac{2}{\pi} \text{Im} \lim_{z \downarrow E} \int_{\Omega_i} G(z, \mathbf{r}, \mathbf{r}) d\mathbf{r}, \quad (10)$$

where $G(z, \mathbf{r}, \mathbf{r}') = \langle \mathbf{r} | G | \mathbf{r}' \rangle$. Of course, the DOS for the supercell is $\rho(E) = \sum_{i=1}^N \rho_i(E)$. The Green's functions and scattering operators that will be used henceforth are obtained from the above by letting z approach E from above the real axis.

When the position vectors $\mathbf{r}$ and $\mathbf{r}'$ are in the region Ω_n , the Green's function in the position representation can be shown to take the form

$$G(E, \mathbf{r}_n, \mathbf{r}'_n) = \sum_{LL'} Z_L^n(E, \mathbf{r}_n) \tau_{LL'}^{nn}(E) Z_{L'}^{n*}(E, \mathbf{r}'_n) - \sum_L Z_L^n(E, \mathbf{r}_n) J_L^{n*}(E, \mathbf{r}'_n), \quad (11)$$

where

$$\tau_{LL'}^{nn} = t_{LL'}^n + \sum_{L_1, L_2, L_3, L_4} t_{LL_1}^n \sum_{i \neq n, j \neq n} g_{L_1 L_2}^{ni} \tau_{L_2 L_3}^{ij} g_{L_3 L_4}^{jn} t_{L_4 L'}^n = t_{LL'}^n + \sum_{L_1, L_2} t_{LL_1}^n \sum_{i \neq n} g_{L_1 L_2}^{ni} \tau_{L_2 L'}^{in}, \quad (12)$$

and $t_{LL'}^n(E)$ is the scattering matrix for the n th atom. The matrix τ with elements $\tau_{LL'}^{mn}$ is the inverse of the matrix $\mathbf{M}$ that has elements,

$$M_{LL'}^{mn} = m_{LL'}^{nn} \delta_{mn} - g_{LL'}^{mn} (1 - \delta_{mn}). \quad (13)$$

The function $Z_L^n(E, \mathbf{r}_n)$ is the solution of the equation,

$$\left[-\frac{\hbar^2}{2m} \nabla^2 + v_n(\mathbf{r}_n) - E \right] Z_L^n(E, \mathbf{r}_n) = 0, \quad (14)$$

that is regular at the origin and joins smoothly to

$$Z_L^n(E, \mathbf{r}_n) \rightarrow \sum_{L'} Y_{L'}(\mathbf{r}_n) j_{L'}(\alpha r_n) m_{L'L}^n(E) - i\kappa Y_L(\mathbf{r}_n) h_L(\alpha r_n), \quad (15)$$

when $\mathbf{r}$ is outside of Ω_n . As usual, $j_l(\alpha r_n)$ and $h_l(\alpha r_n)$ are the spherical Bessel and Hankel functions, and $Y_L(\mathbf{r}) = Y_{l, m}(\vartheta, \phi)$ is the spherical harmonic. The matrix $\mathbf{m}^n$ with elements $m_{LL'}^n$ is the inverse of the scattering matrix $\mathbf{t}^n$ whose elements are

$$t_{LL'}^n(E) = \int \int j_l(xr) Y_L^*(\mathbf{r}) \langle \mathbf{r} | t(E) | \mathbf{r}' \rangle Y_{L'}(\mathbf{r}') j_{l'}(xr') d\mathbf{r} d\mathbf{r}'. \quad (16)$$

The function $J_l^n(E, \mathbf{r}_n)$ is a real solution of the differential equation (14) that joins smoothly to $Y_L(\mathbf{r}_n) j_l(\kappa r_n)$ when $\mathbf{r}$ is outside of Ω_n . The $g_{LL'}^{nm}$ in Eq. (12) can be pictured as propagators that take an electron from site n to m , and are given by

$$g_{LL'}^{nm} = -4\pi i k l^{-l'} \sum i^{-l} C_{LL'}^\Lambda h_\lambda(\kappa R_{nm}) Y_\Lambda^*(\mathbf{R}_{nm}), \quad (17)$$

where $\mathbf{R}_{nm} = \mathbf{R}_m - \mathbf{R}_n$ and the Gaunt factors $C_{LL'}^\Lambda = \int Y_\Lambda Y_L^* Y_{L'} d\Omega$ are related to Clebsch-Gordon coefficients. This equation for the Green's function is correct for any kind of solid, but it is difficult to calculate except for pure metals, metals with impurities, and alloys using approximations.

Pure metals

The expression for the Green's function, Eq. (11), is greatly simplified for infinite periodic solids. The case of one atom per unit cell will be treated because the extension to more than one atom is straightforward. The atoms are on the sites $\mathbf{R}_i$ of a Bravais lattice. Bloch's theorem follows from the invariance of the crystal under translations,

$$\psi_{\mathbf{k}}(\mathbf{r} + \mathbf{R}_{ij}) = e^{i\mathbf{k} \cdot \mathbf{R}_{ij}} \psi_{\mathbf{k}}(\mathbf{r}). \quad (18)$$

There are only N Bloch vectors, $\mathbf{k}_i$, because of the periodic boundary conditions. It follows that the matrix $\mathbf{g}$ with elements $g_{LL'}^{ij}$ can be put into block diagonal form by transforming it with the matrix $\mathbf{U}$ with elements

$$U_{LL'}^{ij} = 1/\sqrt{N} e^{-i\mathbf{R}_i \cdot \mathbf{k}_j} \delta_{LL'}. \quad (19)$$

$$[\mathbf{U}^\dagger \mathbf{g} \mathbf{U}]_{LL'}^{ij} = g_{LL'}(E, \mathbf{k}_i) \delta_{ij} = \sum_{m=1}^N e^{i\mathbf{k}_i \cdot \mathbf{R}_{0m}} g_{LL'}^{0m}(E), \quad (20)$$

Since the matrices $\mathbf{m}^i$ are the same for every cell, the transformed matrix $\mathbf{U}^\dagger \mathbf{M} \mathbf{U}$ is easily inverted. When the $\mathbf{U}$ matrix is used to transform back and then N is allowed to go to infinity, the scattering path matrix for the periodic crystal is

$$\tau_0^{mn}(E) = \frac{1}{N} \sum_{i=1}^N e^{-i\mathbf{k}_i \cdot \mathbf{R}_{mn}} [\mathbf{m}(E) - \mathbf{g}(E, \mathbf{k}_i)]^{-1} = \frac{\Omega}{(2\pi)^3} \int e^{-i\mathbf{k} \cdot \mathbf{R}_{mn}} [\mathbf{m}(E) - \mathbf{g}(E, \mathbf{k})]^{-1} d\mathbf{k}. \quad (21)$$

We suppress the angular momentum indices L and L' in this and succeeding equations by the use of block matrices.

The functions $\mathbf{g}(E, \mathbf{k})$ are called structure constants in Korringa-Kohn-Rostoker (KKR) band theory, and sophisticated methods have been developed for calculating them. The standard approximation in the application of this formula is that the elements of $\mathbf{m}(E)$ and $\mathbf{g}(E, \mathbf{k})$ that correspond to angular momenta such that $l > l_{\max}$ are ignored. Thus, the matrices that must be inverted in Eq. (21) have dimension $(l_{\max} + 1)^2$.

Impurities in metals

When an impurity atom replaces one of the atoms in a periodic metal, the scattering matrix $\mathbf{m}^i$ will obviously change on the impurity site. The scattering matrices on the adjoining sites will also change because of the effect that the impurity has on its neighboring atoms. Even the Green's functions $\mathbf{g}^{ij}$ that connect the atoms affected by the impurity will change, because the size difference between the impurity atom and the host atoms will cause displacements from the sites of the original periodic lattice. In metals, it is reasonable to assume that the influence of the impurity is screened beyond a certain number of nearest neighbor shells to the point that it has no noticeable effect on the rest of the lattice. It follows that the $N \times N$ matrix $\mathbf{M}$ for the metal with an impurity can be written $\mathbf{M} = \mathbf{M}_0 + \Delta\mathbf{M}$, where $\Delta\mathbf{M}$ is a matrix with elements

$$\Delta M_{LL'}^{mn} = (m_{LL'}^n - m_{0LL'}^n) \delta_{mn} - (g_{LL'}^{mn} - g_{0LL'}^{mn})(1 - \delta_{mn}). \quad (22)$$

In this equation, $m_{0LL'}^n$ and $g_{0LL'}^{mn}$ are the matrix elements of the original periodic solid. All of the elements of $\Delta\mathbf{M}$ are zero except for those associated with the N_I sites of the atoms that are influenced by the impurity. Assuming that this is one or two nearest-neighbor shells, N_I is 13 or 19 for an fcc lattice and it is 9 or 15 for a bcc lattice.

Let us call the set of sites influenced by the impurity S_I . If $n \in S_I$, the coefficients $\tau_{LL'}^{mn}$ that appear in the expression for the Green's function in Eq. (11) are elements of the matrix

$$\boldsymbol{\tau}^I = [\mathbf{I} - \boldsymbol{\tau}_0^I \Delta\mathbf{M}^I]^{-1} \boldsymbol{\tau}_0^I. \quad (23)$$

The elements of τ_0^l are the matrix elements of the scattering path operators for the host lattice τ_0^{mn} , where $m \in S_I$ and $n \in S_I$. The matrix ΔM^l contains only the non-zero elements of ΔM . No angular momentum indices are included beyond $l_{\max}$, so the dimension of the matrices in Eq. (26) is $N_I(l_{\max} + 1)^2$.

The best way to calculate the DOS and charge density associated with the sites influenced by the impurity is

$$\rho_n^l(E) = -\frac{1}{\pi} \text{Im} \sum_{LL'} \tau_{LL'}^{l,nn}(E) \int_{\Omega_n} F_{LL'}^n(E, \mathbf{r}, \mathbf{r}) d\mathbf{r}, \quad (24)$$

and

$$\rho_n^l(\mathbf{r}) = -\frac{1}{\pi} \text{Im} \sum_{LL'} \int_{-\infty}^{E_F} \tau_{LL'}^{l,nn}(E) F_{LL'}^n(E, \mathbf{r}, \mathbf{r}) dE, \quad (25)$$

where $F_{LL'}^n(E, \mathbf{r}_n', \mathbf{r}_n) = Z_{LL'}^{n*}(E, \mathbf{r}_n') Z_{LL'}^n(E, \mathbf{r}_n)$. In summary, we assume a charge density for the host atoms and a crystal structure. We use the DFT to calculate the potential for the host atoms, $V_0(\mathbf{r})$, and hence the scattering matrix $\mathbf{t}_0(E)$. We obtain the coefficients $\tau_{0,LL'}^{nn}$ from Eq. (21) and then calculate the Green's function using Eq. (11) and the charge density using Eq. (2). This process is iterated until the charges are self-consistent. At this point we have the coefficients for all the sites of the host lattice, and we have the elements of the matrix τ_0^l . It is now necessary to guess charge densities for the impurity sites with $n \in S_I$, calculate the potentials and scattering matrices, and construct the matrix ΔM^l . The coefficients and Green's functions for these sites are obtained from Eqs. (23) and (11). The Fermi energy is not changed, and the new charge densities at the impurity sites are obtained from Eq. (25). The potentials must be iterated to self-consistency. These formulas have been very successful in predicting resistivities, hyperfine energies, and energies of formation, but only if the relaxation of the atoms in the nearest-neighbor shells away from the periodic lattice sites is allowed to occur. The calculations are sensitive to approximations to the shape of the self-consistent potentials, and, where relevant, spin polarization must be included.

An interesting formula for the DOS can be obtained using a theorem from scattering theory derived by the Russian academician M. G. Krein. In operator language, Krein's theorem states that

$$\text{Tr}[G(z) - G_0(z)] = \frac{i}{2\pi} \lim_{\varepsilon \downarrow 0} \int_{-\infty}^{\infty} \frac{\ln \det(I - i2\sqrt{E' + i\varepsilon} T(E' + i\varepsilon))}{(E' - z)^2} dE'. \quad (26)$$

Using the formula for the DOS in Eq. (10), this equation can, with some effort, be put into the form

$$\rho(E) - \rho_0(E) = -\frac{2}{\pi} \text{Im} \frac{d \ln \det \mathbf{M}(E)}{dE}, \quad (27)$$

where $\rho(E)$ is the DOS for the system of scatterers, $\rho_0(E)$ is the DOS for free electrons, and $\mathbf{M}(E)$ is the matrix defined in Eq. (13). This is called Lloyd's formula because Lloyd derived it without the help of Krein's theorem. Krein's theorem can immediately be used for impurities by defining H_0 to be the Hamiltonian for the host lattice rather than just the kinetic energy, and a version of Lloyd's formula that gives the change in the total DOS caused by the impurity can be obtained.

The simplest theory for an impurity is to picture it as a single spherically-symmetric scatterer embedded in a free-electron gas. Then Krein's theorem leads to

$$\rho(E) - \rho_0(E) = -\frac{i}{\pi} \text{Im} \sum_l (2l + 1) \frac{d \ln[1 - 2\alpha t_l(E)]}{dE}. \quad (28)$$

For such a scatterer, the t-matrix defined in Eq. (16) becomes $t_{LL'} = t_l \delta_{ll'} \delta_{mm'}$ with

$$t_l = -\frac{1}{\alpha} e^{i\eta_l} \sin \eta_l, \quad (29)$$

where the η_l are scattering phase shifts. From this, we obtain the Friedel sum

$$\rho(E) - \rho_0(E) = \frac{2}{\pi} \sum_l (2l + 1) \frac{d\eta_l}{dE}. \quad (30)$$

The Friedel formula appears in many text books on condensed matter physics, but the assumptions that go into its derivation are very limiting. Leaving aside the fact that the electronic spectrum of the host resembles a free electron gas for very few solids, the assumption that the change in the spectrum is confined to one site is internally inconsistent. It is typical that the impurity atom loses or gains charge from the host. The charge will be screened to make the system charge neutral, but the screening charge is typically distributed over one or two nearest-neighbor shells.

Coherent potential approximation

It should be clear that the impurity equations described in the preceding section can be generalized to deal with several interacting impurities in a metal. It is only necessary to increase the number of sites N_i influenced by the impurity atoms. However, when the concentration of impurities reaches the point at which most of the impurity atoms are within range of each other, the impurity equations are no longer useful. It is then necessary to treat the material as an alloy, and to develop a different class of theories. The problem of finding the solutions of Schroedinger's equation for a potential function that is not periodic is difficult because Bloch's theorem, Eq. (18), no longer holds. Progress has been made on substitutional solid-solution alloys that are made up of two or more species of atoms distributed randomly on the sites $\mathbf{R}_i$ of a Bravais lattice. In the following, we concentrate on binary alloys, although the generalization to ternary, quaternary, etc. is straightforward.

The ensemble of all alloys that can be constructed out of $N_A = c_A N$ A atoms and $N_B = c_B N$ B atoms contains $M_c = N! / N_A! N_B!$ atomic arrangements. Experimentally, it is observed that all alloys with the concentrations c_A and c_B have the same electronic structure. It follows that, as $N \rightarrow \infty$, all of the arrangements have the same electronic structure with probability one, and it can be found by averaging over the ensemble. The ensemble average of a one-electron wave function has no meaning, but, because of the linear relation between the Green's function and the electronic properties, the ensemble average of the Green's function is useful.

The ensemble average of the function in Eq. (11) can be obtained if we make the assumption that the resulting alloy model is isomorphous. That is, we assume that the Green's function takes one of two forms, $G_A(E, \mathbf{r}_n, \mathbf{r}_n')$ if there is an A atom on site n and $G_B(E, \mathbf{r}_n, \mathbf{r}_n')$ if there is an B atom on that site. With this assumption, the ensemble averaged Green's function is

$$\langle G_n(E, \mathbf{r}_n, \mathbf{r}_n') \rangle = c_A G_A(E, \mathbf{r}_n, \mathbf{r}_n') + c_B G_B(E, \mathbf{r}_n, \mathbf{r}_n'), \quad (31)$$

where

$$G_A(E, \mathbf{r}_n, \mathbf{r}_n') = \sum_{LL'} Z_L^A(E, \mathbf{r}_n) \langle \tau_{LL'}^{nn} \rangle_A Z_{L'}^{A*}(E, \mathbf{r}_n') - \sum_L Z_L^A(E, \mathbf{r}_n) J_L^{A*}(E, \mathbf{r}_n'), \quad (32)$$

and

$$G_B(E, \mathbf{r}_n, \mathbf{r}_n') = \sum_{LL'} Z_L^B(E, \mathbf{r}_n) \langle \tau_{LL'}^{nn} \rangle_B Z_{L'}^{B*}(E, \mathbf{r}_n') - \sum_L Z_L^B(E, \mathbf{r}_n) J_L^{B*}(E, \mathbf{r}_n'). \quad (33)$$

The charge density for an A atom, $\rho_A(\mathbf{r}_n)$, is obtained by inserting $G_A(E, \mathbf{r}_n, \mathbf{r}_n)$ into Eq. (2), and similarly for the B atom. From these charge densities we calculate the potentials $v_A(\mathbf{r}_n)$ and $v_B(\mathbf{r}_n)$. The functions $Z_L^A(E, \mathbf{r}_n)$ and $J_L^A(E, \mathbf{r}_n)$ are obtained using $v_A(\mathbf{r}_n)$ in Eq. (13), and the functions $Z_L^B(E, \mathbf{r}_n)$ and $J_L^B(E, \mathbf{r}_n)$ are obtained using $v_B(\mathbf{r}_n)$.

The averages $\langle \tau_{LL'}^{nn} \rangle_A$ and $\langle \tau_{LL'}^{nn} \rangle_B$ are the ensemble averages of the scattering path operator subject to the condition that there is an A or B atom on site n . These averages are simplified considerably by making a mean field approximation. It is assumed that, on average, the scattering of the electrons from all the sites other than site n is described by replacing the actual potentials on those sites with a potential $v_c(\mathbf{r})$, called the coherent potential. The scattering from $v_c(\mathbf{r})$ is described by a t-matrix, $\mathbf{t}_c(E)$, which has an inverse $\mathbf{m}_c(E)$. It follows that, within the coherent potential approximation (CPA) (Faulkner, 1982), the ensemble averages $\langle \tau_{LL'}^{nn} \rangle_A$ and $\langle \tau_{LL'}^{nn} \rangle_B$ are the elements of the matrices obtained from Eq. (23)

$$\langle \tau^{nn} \rangle_A = [\mathbf{I} - \tau_c^{nn}(\mathbf{m}_A - \mathbf{m}_c)]^{-1} \tau_c^{nn}, \quad (34)$$

and

$$\langle \tau^{nn} \rangle_B = [\mathbf{I} - \tau_c^{nn}(\mathbf{m}_B - \mathbf{m}_c)]^{-1} \tau_c^{nn}. \quad (35)$$

The matrices $\mathbf{m}_A$ and $\mathbf{m}_B$ are the inverses of the t-matrices calculated from the potentials $v_A(\mathbf{r})$ and $v_B(\mathbf{r})$. From Eq. (24), it can be seen that the matrix τ_c^{nn} is

$$\tau_c^{nn}(E) = \frac{\Omega}{(2\pi)^3} \int [\mathbf{m}_c(E) - \mathbf{g}(E, \mathbf{k})]^{-1} d\mathbf{k}. \quad (36)$$

The number of impurity sites N_I is one, so the matrices in these equations have dimension $(l_{\max} + 1)^2$. As would be expected, none of these equations depend on the choice of a site n .

In the language of multiple-scattering theory used here, the condition originally put forward by P. Soven that defines the mean field t-matrix $\mathbf{t}_c(E)$ is

$$c_A \langle \tau^{nn} \rangle_A + c_B \langle \tau^{nn} \rangle_B = \tau_c^{nn}. \quad (37)$$

In words, this is the condition that, on average, there is no scattering from A and B atoms embedded in the coherent potential host matrix. Space does not allow for descriptions of all the arguments put forward to justify this CPA condition. Perhaps the most convincing arguments come from the formulation of the problem of calculating the Green's function of an alloy in terms of infinite order perturbation theory. Diagrams are then used to analyze the contributions to the Green's functions in a manner analogous to field theory, quantum electrodynamics, or many-body theory. It has been argued that the CPA contains the maximum number of

classes of diagrams that can be included and still retain a Green's function that is properly analytic. The criterion that is used to specify the diagrams included in the CPA is called the single-site approximation. It has been shown by R. Mills and P. Ratanavararaksa and also A. Mookerjee that it is possible to go beyond the single-site approximation and retain an analytic Green's function, but it is difficult.

The procedure for calculating the electronic states within the CPA is first to guess starting values for the charge densities $\rho_A(\mathbf{r})$ and $\rho_B(\mathbf{r})$ and from them calculate $v_A(\mathbf{r})$ and $v_B(\mathbf{r})$. The t -matrices $t_A(E)$ and $t_B(E)$ are calculated, and a first guess to $t_c(E)$ is just the average of them $t_c(E) \approx c_A t_A(E) + c_B t_B(E)$. Eqs. (32)–(35) are then iterated to self-consistency in the charge densities and also in the coherent potential t -matrix $t_c(E)$.

Calculations with this version of the CPA have been carried out on many alloy systems. The predicted electronic densities of states agree well with the ones measured in ultraviolet photoemission spectroscopy experiments. The zero temperature resistivities of alloys have been accurately predicted. Even the propensity of a random alloy to transform into a superlattice structure or into an incommensurately ordered structure has been successfully predicted.

A problem that is endemic to this version of the CPA is that the Coulomb effects are not treated correctly. Integrating the charge densities $\rho_A(\mathbf{r})$ and $\rho_B(\mathbf{r})$ and subtracting the nuclear charges Z_A and Z_B leads to the net charges on the A and B sites, q_A and q_B . It would seem that there should be a Madelung contribution to the potentials $v_A(\mathbf{r})$ and $v_B(\mathbf{r})$ as in ordered alloys, but the only Madelung potentials that are commensurate with the assumption of an isomorphous alloy are zero. The isomorphous model of an alloy with the charge q_A on every A atom and q_B on every B atom is not realistic. Using order- N methods that will be described in the next section, it is possible today to calculate the electronic structure for supercells containing thousands of atoms with no approximation other than the DFT. In Fig. 1 we show the charges on 512 copper atoms and 512 zinc atoms distributed randomly on the sites of a supercell with the structure of a body centered cubic lattice. The distribution is broad, and upon reflection is what would be expected on the basis of physical intuition. It should be compared with the prediction of the isomorphous model that all the Cu atoms would take on exactly 0.09978 electron charges, and Zn atoms would lose the same amount.

A version of the CPA can be constructed that leads to a polymorphous model of the alloy in which each atom has a different charge, but it requires a different kind of averaging. Recall that we consider periodically reproduced supercells. In the binary alloy model, N_A A atoms and N_B B atoms are distributed over the $N = N_A + N_B$ sites. The green's function defined in Eq. (11) for the alloy is different for each of the $M_c = N! / N_A! N_B!$ possible atomic arrangements, and can be labeled $G_n^i(E, \mathbf{r}_n, \mathbf{r}_n')$ to emphasize that. Then, the ensemble average in Eq. (27) can more properly be written

$$\langle G_n(E, \mathbf{r}_n, \mathbf{r}_n') \rangle = \frac{1}{M_c} \sum_{i=1}^{M_c} G_n^i(E, \mathbf{r}_n, \mathbf{r}_n'). \quad (38)$$

It is also possible to consider one supercell with the atomic arrangement i , and average over the sites

$$\{G^i(E, \mathbf{r}, \mathbf{r}')\} = \frac{1}{N} \sum_{n=1}^N G_n^i(E, \mathbf{r}, \mathbf{r}'). \quad (39)$$

We have seen that, as $N \rightarrow \infty$, $\langle G_n(E, \mathbf{r}_n, \mathbf{r}_n') \rangle$ is independent of the site index n . It is equally clear that in the same limit, $\{G^i(E, \mathbf{r}, \mathbf{r}')\}$ is independent of the arrangement index i . The equivalence of the ensemble-average in Eq. (38) with the site average in Eq. (39) is

Fig. 1 The distribution of charges on the sites of a 50% copper-zinc alloy modeled with a supercell containing 1024 atoms. The charges on the copper sites are shown with the white histograms, and the charges on the zinc sites are cross-hatched. Created by the author using KaleidaGraph.

similar to the Ergodic theorem first proposed by Boltzmann, and can be proved by similar arguments. If the condition is imposed that the alloy must be isomorphous, the site average will lead to the same averaged potential as the ensemble average result shown in Eq. (27). However, the site average can lead to a polymorphous model.

Applying the CPA philosophy to the site averaged Green's function leads to

$$\{G(E, \mathbf{r}, \mathbf{r}')\} = \frac{1}{N} \sum_{n=1}^N \{G_n(E, \mathbf{r}, \mathbf{r}')\}, \quad (40)$$

where

$$\{G_n(E, \mathbf{r}, \mathbf{r}')\} = \sum_{LL'} Z_L^n(E, \mathbf{r}) \{\tau_{LL'}^{nn}(E)\} Z_{L'}^n(E, \mathbf{r}') - \sum_L Z_L^n(E, \mathbf{r}) J_L^n(E, \mathbf{r}'), \quad (41)$$

and

$$\{\tau^{nn}\} = [\mathbf{I} - \tau_c^{nn}(\mathbf{m}_n - \mathbf{m}_c)]^{-1} \tau_c^{nn}. \quad (42)$$

Inserting the Green's function for an index n into Eq. (2) produces a charge density, $\rho_n(\mathbf{r})$, and hence a one-electron potential, $v_n(\mathbf{r})$, for every site. From the potential, we calculate the t -matrix $\mathbf{t}_n$ and its inverse $\mathbf{m}_n$ which appears in Eq. (38). As in the isomorphous CPA, the scattering path for the coherent potential host lattice τ_c^{nn} is calculated from Eq. (36). The condition that defines the coherent potential is

$$\frac{1}{N} \sum_{n=1}^N \{\tau^{nn}\} = \tau_c^{nn}, \quad (43)$$

instead of Eq. (37).

Since we are focusing on a specific supercell, the position $\mathbf{R}_n$ of each atom is known and the Madelung potential for the n th site is

$$v_n^M = \sum_{m \neq n=1}^N M(|\mathbf{R}_n - \mathbf{R}_m|) q_m, \quad (44)$$

where

$$q_n = \int_{\Omega_n} \rho_n(\mathbf{r}) d\mathbf{r} - Z_n, \quad (45)$$

and $M(|\mathbf{R}_n - \mathbf{R}_m|)$ is the Madelung matrix. The Madelung matrix is defined so that the sum in Eq. (44) gives the contribution to the Coulomb potential from all of the periodically reproduced supercells. A sophisticated method for calculating it was developed by P. P. Ewald, and it reduces to $1/|\mathbf{R}_n - \mathbf{R}_m|$ when $N \rightarrow \infty$. The potentials $v_n(\mathbf{r})$ contain the Madelung shift v_n^M .

The polymorphous version of the CPA has been applied to several alloy systems. For alloys that have a large amount of charge transfer, such as copper-gold or copper-palladium, it gives better results than the ones obtained with the isomorphous CPA, but the improvements are quite small for alloys like silver-palladium that have a small charge transfer. The polymorphous CPA has the disadvantage that it requires the use of a specific supercell. This is a small price to pay for the improvement in the treatment of the Coulomb energy. It is quite easy to apply because the charge densities $\rho_A(\mathbf{r})$ and $\rho_B(\mathbf{r})$ and the effective t -matrix $\mathbf{t}_c$ from the isomorphous CPA are used as the starting values in the self-consistent iterations.

Although the coherent potential $v_c(\mathbf{r})$ is introduced into the discussion, it is never calculated or used. The only potentials used in Eq. (14) to calculate wave functions are real potentials for real atoms, $v_n(\mathbf{r})$. From the analytic properties of $\mathbf{t}_c$ it follows that $v_c(\mathbf{r})$, if it existed, would be complex and energy-dependent.

Order-N methods

A brute force method for calculating the electronic states of a disordered solid is to simply model a portion of the solid in a supercell. The nuclei do not have to be placed on the sites of a Bravais lattice, and any combination of atomic species can be used. This makes it possible to approach a much wider range of problems than the CPA can deal with. Supercells containing a large number of atoms can be treated with the band-theory methods that have been developed to treat solids with N atoms per unit cell. All of these methods require an operation that is the equivalent of inverting or diagonalizing an $N \times N$ matrix, and these operations require an amount of computer time that scales as N^3 . Even though computer speeds increase exponentially, this scaling always places a limit on the size of the supercell that can be used. For this reason, considerable effort has been devoted to the development of order- N methods for electronic structure calculations for which the computer times scale as N rather than N^3 .

An order- N method called the locally self-consistent multiple-scattering (LSMS) method was developed by G. M. Stocks and his collaborators (Yang Wang et al., 1995). Each atom in the supercell is considered to be the center of a cluster of a local interaction zone (LIZ) that contains N_{LIZ} atoms. The matrix $\mathbf{M}^n$ with elements defined in Eq. (13) is truncated so that only the scatterers in the LIZ corresponding to site n are included. This is typically the n th site and its first seven or eight nearest neighbor shells. Truncating

the angular momentum expansions at $l_{\max}$, the order of $\mathbf{M}^n$ is $(l_{\max} + 1)^2 N_{\text{LIZ}}$ and $N_{\text{LIZ}} < 100$. After the inversion of $\mathbf{M}^n$, only the matrix elements $\tau_{LL'}^m$ corresponding to the central atom are used. With these matrix elements, the Green's function $G_n(E, \mathbf{r}_n, \mathbf{r}_n')$ is calculated from Eq. (11), and hence the charge density $\rho_n(\mathbf{r}_n)$ and the net charge on the site q_n are obtained. The Madelung shift on the n th site is calculated using Eq. (44), and the next iteration for the potential $v_n(\mathbf{r})$ is acquired by adding that to the DFT potential calculated from the charge density. This procedure scales with N , although the prefactor is $(l_{\max} + 1)^6 N_{\text{LIZ}}^3$.

The LSMS puts nothing on the sites outside the LIZ. The locally self-consistent Green's function (LSGF) method proposed by I. A. Abrikosov and his collaborators puts coherent potentials on those sites. The LSGF makes use of the equations for an impurity cluster in a metal, Eqs. (22)–(25), with the coherent potential scattering matrix $\mathbf{m}_c$ replacing the host matrix $\mathbf{m}_0$. The matrix $\boldsymbol{\tau}^I$ in Eq. (23) contains the average scattering path operators for all the scatterers in the LIZ. Only the matrix for the central site, $\{\boldsymbol{\tau}^m\}$, is used in the equation that defines $\mathbf{m}_c$, which is Eq. (43). The charge density $\rho_n(\mathbf{r}_n)$ is obtained by inserting the Green's function from Eq. (41) into Eq. (2). This charge density and the Madelung shift from Eq. (44) is used to calculate the new potential $v_n(\mathbf{r})$ in the self-consistent process.

The LSMS has the advantage that the atoms can be placed anywhere in the supercell, while the atoms should be on the sites of a Bravais lattice in the LSGF. The advantage of the LSGF is that the LIZ can be made much smaller. In fact, for $N_{\text{LIZ}} = 1$, which means that it contains only the central atom, the LSGF is identical to the site-averaged CPA described above. That level of approximation is adequate for many calculations on alloys.

The LSMS and LSGF are order- N because the propagation of electrons from one atom to another is treated properly only for atoms within the LIZ. It should be noted that the range of the Coulomb interactions is not assumed to be short. The Ewald sum in Eq. (44) includes the contributions from all the atoms in the supercell, and indeed from the atoms in the periodically reproduced supercells that fill all space. The calculation of the Madelung shifts takes very little time in comparison with the rest of the calculation, and experience has shown that it is not a good idea to truncate it.

Extensions and approximations

All of the equations in this article have been written in the non-relativistic form because they are easier to picture. They can easily be transformed to the Dirac form using the relativistic density functional theory (RDFT) of A. K. Rajagopal and others. The spin-polarized version of these equations has been used very successfully to explain the magnetism of metals and alloys. Instead of using the full multiple-scattering version of the equations depicted here, many authors choose to approximate them with a variational version called the linear combination of muffin-tin orbitals (LMTO). These approximations are discussed for wave functions (Faulkner, 2016).

The amount of computer time required for calculations with Green's functions can be significantly reduced with the help of sophisticated techniques derived from their properties. Using the analyticity of the Green's functions, it is frequently possible to carry out integrals over the energy, such as Eq. (2), by making the energy complex and integrating over a contour rather than along the real axis. It is also possible to use a finite-temperature version of the DFT that improves the convergence of some of the integrals. Finally, the range of the propagators $\mathbf{g}^m$ that describe the motion of the electron from one site to another can be made short by shifting the zero of the potential between scatterers.

Of course, many properties of alloys are calculated using statistical methods such as Monte Carlo, molecular dynamics, and the cluster-variational method. The electronic structure appears in these calculations only in the calculation of the interatomic potentials. Different approaches to the calculation of these potentials are the embedded atom method, the generalized perturbation method, and the mixed-space cluster expansion method.

Conclusion

Modern computer suites such as the ones provided by the MuST group use the theory outlined above to study complex phenomena in the fields of condensed matter physics and materials science. They normally operate on highly parallel computers like the Summit 200 petaflop supercomputer at the Oak Ridge National.

Abstract

This chapter describes the origins and classification of aluminum alloys; main types of heat treatments regimes, basic types of processing and related microstructural features. The principles of aluminum alloys design as applicable to different types of aluminum alloys are discussed. Main applications of aluminum alloys are summarized.

Key points

- Importance of aluminum alloys for modern applications
- Heat treatable and not heat treatable aluminum alloys: limitations and advantages
- Main processing routes for aluminum alloys
- Microstructure evolution upon solidification and deformation; main microstructural features
- Alloy design and applications of aluminum alloys

Introduction

Aluminum (Al) is the third most abundant element and the most common metal (8% in mass) in the Earth crust; but because it is very reactive with oxygen and some other elements it is not found in the native state but mostly in a form of mixed oxides, hydroxides and aluminosilicates (Altenpohl, 1998). The most important ore containing aluminum is bauxite but nepheline, kaolin, and alunite are also used. Sir Humphrey Davy (England) in 1808 predicted that alumina is an oxide of a then unknown element that he called “aluminum” though he was not successful in extracting it. This name is still used in the USA and Canada though the rest of the world adopted the term “aluminium.” Hans Christian Oersted (Denmark) in 1825 isolated aluminum in a pure form. 2 year later Friedrich Wohler (Germany) produced small amounts of aluminum and in 1845 tested some of physical and mechanical properties, demonstrating its light weight and high ductility. First production of aluminum started in 1855 by Henri Sainte-Claire Deville (France) using electrolytical reduction of aluminum chloride by potassium and sodium. The produced aluminum was more expensive than gold being used for jewelry and as expensive tableware. During the construction of the Washington Monument, the world’s tallest structure of that period, a material was needed to top off the structure, serving as a lustrous apex and a lightning rod. A cast aluminum pyramid 2.83 kg in weight was produced by William Frishmuth in 1884 and mounted on the top. It was the largest aluminum casting for that time, cost a fortune and was the first architectural application of this metal. Two years later the price for Al went down due to the invention of a new production process. In the 1890s, aluminum was used by Alfred Gilbert to cast a famous statue of Anteros (a.k.a. Eros) in Piccadilly Circus in London, the first sculpture made of aluminum taking advantage of its lightness and corrosion resistance.

In 1886, Charles Martin Hall in the USA and Paul-Louis Toussaint Héroult in France independently developed an economically viable method of producing aluminum, which ultimately led to its widespread use throughout the world. Their invention replaced

[☆]Change History: August 2022. DG Eskin prepared the update. All sections of the articles were amended/updated with the following new items: Main features and classification of aluminum alloys; Alloys for additive manufacturing. Figs. 1A, B, and Tables 1, 2 are new. Significantly updated list of references.

the chemical reduction process with electrolytic reduction alumina using carbon anodes. In this energy-intensive process, a solution of alumina in a molten mixture of cryolite (Na_3AlF_6) with calcium fluoride is electrolyzed to produce metallic 99% pure aluminum. Austrian chemist Carl Joseph Bayer discovered a way of enriching bauxite to yield alumina, known as the Bayer process, in 1889. These two processes have lowered metal's cost from \$15/pound in 1884 to \$0.50/pound in 1890. Modern production of the aluminum is based on the Bayer and Hall–Héroult processes. Some novel developments include the use of inert anodes (e.g., NiO and SnO_2) to eliminate carbon emissions. The production of aluminum remains energy consuming and, therefore, it concentrated in the countries with abundant sources of cheap electricity such as hydro (China, India, Russia, Norway, Canada), natural gas (United Arab Emirates) and geothermal (Iceland). The versatility of aluminum has resulted in it replacing many older, more established materials, and it is now produced and consumed, on a volumetric basis, more than all other nonferrous metals combined, including copper, magnesium, lead, and zinc. High energy costs and environmental impact of primary aluminum production necessitate recycling. The production of aluminum from bauxite requires about 17,000 kWh/ton of electricity, while the same amount of recycled aluminum consumes approximately 750 kWh (Totten et al., 2019). Therefore, the recycled aluminum substitutes primary aluminum with an energy gain of 95%. Aluminum and its alloys are highly recyclable with almost 85% of all ever produced aluminum still in circulation. Current efforts are focused on increasing the proportion of recycled aluminum closer to 100%.

Main features and classification of aluminum alloys

Aluminum is silver in color, light and ductile metal with good electrical and thermal conductivity, and high corrosion resistance (Mondolfo, 1976; Davis, 1993; Polmear, 1995). It has a low density of 2.7 g cm^{-3} compared to that of iron (7.9 g cm^{-3}), copper (8.96 g cm^{-3}) and titanium (4.5 g cm^{-3}) due to its low atomic mass of 27. The high ductility and isotropic formability of aluminum are due to the high symmetry and thermodynamic stability of the face-centered cubic (f.c.c.) crystal lattice and its high stacking-fault energy (162 mJ/m^2). In the pure form, aluminum has a low stiffness (Young's modulus, E) of 70 GPa compared to 211 GPa for Fe or 116 GPa for Ti; and a low tensile strength of 90 MPa, compared to 280 MPa for Fe and 240 MPa for Ti. However, its specific modulus, i.e., modulus divided by density, is almost equal to that for iron, titanium, and magnesium. An advantageous chemical property of aluminum is its reactivity with oxygen, which leads to the formation of a strong thin film of Al_2O_3 on the surface, which shields the base metal from further environmental interactions. The electrical and thermal conductivity of solid aluminum are $26.5 \text{ n}\Omega \text{ m}$ (at 20°C) and 237 W (m K)^{-1} , respectively. This makes Al a light and cheap alternative to copper as an electric conductor (61% IACS). With taking into account the density, a wire of aluminum weighs half as much as a wire of copper that has the same electrical conductivity.

Pure aluminum is not, however, used commercially because of its low strength. The mechanical and functional properties of aluminum are improved by alloying. Alloying elements in aluminum can be classified by the type of solidification reactions with aluminum and the variation of solubility in the solid aluminum. Most common main alloying elements and impurities in Al alloys have a eutectic type of solidification in the Al-rich corner of the phase diagram; these are Si, Cu, Mg, Zn, Ni, Fe, Li, Ag, Ca, Sn, Sb (Mondolfo, 1976; Belov et al., 2005). Transition elements that are usually added to Al alloys for grain control during solidification and recrystallization through dispersoid formation have typically a peritectic reaction with Al during solidification (Ti, Zr, Nb, Cr, Ta, Hf, V, Mo) with notable exceptions of Mn and Sc that have a eutectic type of the phase diagram with Al (Mondolfo, 1976; Belov et al., 2005). Rare-earth metals that are sometimes added for dispersion hardening and structure control (Ce, Er, La, Ho, Nd, Re, Sm, Y, Yb) have a eutectic reaction with Al (Mondolfo, 1976; Belov et al., 2005). A small group of alloying elements form a miscibility gap in the liquid state and are used in free-machining and self-lubricating alloys, e.g., Bi, Cd, Pb, In (Mondolfo, 1976; Davis, 1993). Among the alloying elements that have large solubility in the solid aluminum (this solubility typically decreases with temperature making possible supersaturation, solution hardening and precipitation hardening) are Ag (55.6 wt%), Zn (31.6 wt%), Mg (17.4 wt%), Cu (5.7 wt%), Li (4.2 wt%), Si (1.6 wt%), Mn (1.8 wt%) (Mondolfo, 1976). Transition elements such as Zr, Ti, Sc tend to form supersaturated solid solutions in aluminum upon solidification with a sufficiently high cooling rate, opening way to dispersion hardening upon annealing (Toropova et al., 1998).

A major metallurgical development in alloy design occurred in 1906 when Alfred Wilm (Germany) accidentally discovered the process of “age hardening” in Al-Cu alloys. He was conducting research directed toward improving the strength of aluminum alloys. He knew that steel could be strengthened if the right compositions were cooled fast enough from high temperatures, so following this recipe he heated some Al-(3.5–5.5) wt% Cu alloys, plus less than 1% magnesium and manganese, to a high temperature and quenched them in water. To his frustration, many of the alloys he tested were softer after quenching than after casting. However, after a few days he found that their hardness and tensile properties had increased considerably. One of the alloys, designated Duralumin, is still in use today. Later, in 1919, P.D. Merica, R.G. Waltenberg, and H. Scott (USA) explained the phenomenon of age hardening as a result of clustering and precipitation of solute atoms from the supersaturated solid solution in a form of phases. However, these nano-microstructural features were too small to be resolved by optical microscopy (not transmission electron microscopes were then available). Only in 1938 the X-ray diffraction studies of A. Guinier (France) and G.D. Preston (UK) allowed them to independently discover the formation of atomic clusters that distorted the crystal lattice and resulted in hardening. These clusters are now called Guinier–Preston zones. Direct proof of nano-scale precipitates was not obtained until the development of transmission electron microscopy in 1959. Since the 1930s the development of alloys that utilize precipitation hardening took off and resulted in the modern alloys of Al-Cu-Mg, Al-Zn-Mg-(Cu), Al-Mg-Si, and Al-Li-Mg-(Cu) groups (Vasudevan and Doherty, 1989; Davis, 1993; Polmear, 1995).

Not all of commercial aluminum alloys are hardened by precipitates. There are also alloys that are hardened by solution hardening, i.e., by solute atoms that are retained in the solid solution and induce strains due to the difference of atomic radii, the most notable are Al-Mg alloys (Sanders et al., 1986; Polmear, 1995).

Therefore, the aluminum alloys are classified as heat-treatable (age-hardenable) or non-heat-treatable (non-age-hardenable), depending on whether or not they undergo precipitation (age) hardening (Polmear, 1995; Totten et al., 2019). There are also two main different product forms of aluminum alloys; i.e., wrought alloys that have been worked or deformed into plates, sheets or profiles from cast billet and ingots (typically made by continuous or semi-continuous casting) and casting (or foundry) alloys that are produced and used in a near-shape “as-cast” condition. Wrought aluminum alloys are normally designated by a four-digit numerical system developed by the Aluminum Association (Davis, 1993; Aluminum Association, 1997). The nomenclature has now been accepted by most countries and is called the International Alloy Designation System (IADS). The system used for casting alloys (three digits) is slightly different from that used for wrought alloys; however, the first digit designates the alloy group (series) and is essentially the same for both wrought and cast alloys. Table 1 gives a summary of the alloying systems.

The 1XXX alloys contain a minimum of 99% aluminum, so this is mostly commercially pure aluminum. In this series, 10XX is used to designate unalloyed compositions that have natural impurity limits. The last two of the four digits in the designation indicate the minimum aluminum percentage, e.g., 1087 means 99.87% pure Al. Alloy grades having second digits other than zero indicate special control of one or more individual impurities. In the 2XXX through 8XXX alloy series, the second digit indicates alloy modification. If the second digit is zero, it indicates the original alloy; integers 1 through 9 indicate modifications of the original alloy, in many cases the purity with regard to Fe and Si. In casting alloys, the second two digits identify the specific aluminum alloy or, for the 1XX.X series, indicate purity. The last digit in casting alloy grades, which is separated from the others by a decimal point, indicates the product form, whether casting (0) or ingot (1). A modification of an original alloy or the impurity limits for unalloyed aluminum are indicated by a letter preceding the numerical designation. The letters are assigned in alphabetical sequence starting with A but omitting I, O, Q, and X, the X being reserved for experimental alloys.

Despite being widely adopted, the Aluminum Association system is not unique, there is also an ISO (The International Organization for Standardization) system accepted in some European countries as well as national alloy grades that are used in Russia, China, Japan, Germany, France etc.

The heat-treatment or temper-nomenclature system developed by the Aluminum Association has also been adopted as part of the IADS by most countries (Davis, 1993; Aluminum Association, 1997; Totten et al., 2019). It is used for all forms of wrought and cast aluminum alloys with the exception of ingots. The system is based on the treatments used to develop the various tempers and takes the form of letters added as suffixes to the alloy number. One or more digits following the letter indicate subdivisions of the tempers, when they significantly influence the characteristics of the alloy. Table 2 summarizes the heat treatment conditions of the alloys.

Alloys supplied in the as-fabricated condition (F) are shaped by cold working, hot working, or casting processes in which no special control over thermal conditions or strain hardening is employed. Annealed wrought products (O) are annealed to obtain lowest-strength temper and annealed cast products—to improve ductility and dimensional stability. Work hardened products (H) are strengthened by strain hardening, with or without supplementary thermal treatment to produce some reduction in strength. Those can be strain hardened only (H1X), strain hardened and annealed (H2X) or strain hardened and stabilized (H3X). Solution treated alloys (W) are unstable and change their properties due to natural aging. Thermally treated alloys (T) encompass: T1 (cooled and naturally aged); T2 (cooled, cold worked and naturally aged); T3 (solution heat treated, cold worked and naturally aged); T4 (solution heat treated and naturally aged); T5 (cooled and artificially aged); T6 (solution heat treated and artificially aged to the maximum hardness); T7 (solution heat treated and overaged or stabilized); T8 (solution heat treated, cold worked and artificially

Table 1 Alloying systems for aluminum alloys according to the Aluminum Association classification (Davis, 1993; Aluminum Association, 1997).

<i>Alloying series of wrought alloys</i>	<i>Main alloying elements</i>	<i>Alloying series of casting alloys</i>	<i>Main alloying elements</i>
1XXX	—	1XX.X	—
2XXX	Cu, Cu + Mg	2XX.X	Cu
3XXX	Mn, Mn + Mg	3XX.X	Si, Si + Mg, Si + Cu
4XXX	Si	4XX.X	Si
5XXX	Mg	5XX.X	Mg
6XXX	Mg + Si	6XX.X	Not in use
7XXX	Zn, Zn + Mg; Zn + Mg + Cu	7XX.X	Zn, Zn + Mg; Zn + Mg + Cu
8XXX	Other elements, e.g., Li, Bi	8XX.X	Sn, Sn + Cu, Sn + Cu + Si
9XXX	Reserved for future use	9XX.X	Not in use

Table 2 Temper designations for aluminum alloys (Aluminum Association, 1997).

<i>Designation</i>	<i>Condition</i>
F	As-fabricated
O	Annealed or recrystallized
H followed by 2 digits	Work hardened
W	Solution heat treated
T followed by 1 or more digits	Thermally treated

aged); T9 (solution heat treated, artificially aged and cold worked) and T10 (cooled, cold worked and artificially aged). Tempers that involve deformation are called thermo-mechanical treatment.

A new class of aluminum alloys is emerging, i.e., alloys for additive manufacturing (Aboulkhair et al., 2019). Those are specifically designed for high cooling rates, structure stability and specific casting properties. Most of them are currently proprietary alloys but maybe unified in a new internationally recognized grade system in the coming years.

Processing of aluminum alloys

The final product from an aluminum alloy can be obtained by a number of methods, i.e., by shape casting in a variety of molds; by deformation of cast billets or ingots; by additive manufacturing; and by compacting and sintering of powders (Polmear, 1995; Altenpohl, 1998; Totten et al., 2019). Only the last technology does not include the melting stage, though melting can be involved in powder making. Shape casting is typically done either in sand (clay) molds (low cooling rate, large and complex shapes) or in metallic molds-dies (higher cooling rate, smaller shapes). For the small and complexly shaped castings, high-pressure die casting or investment (lost wax, lost foam) casting are used. Alloys for subsequent deformation are cast in round billets (rods) or flat ingots (sheets) by a (semi-) continuous casting technology that involves indirect and direct cooling by water (direct-chill casting, Properzi, Hazelett, twin roll casting). Additive manufacturing uses powders or wire to build a complex shape layer-by-layer (hence, another name—3D printing). The rapid remelting of the feedstock is done typically by laser or electron-beam heating.

In fabricating any aluminum alloy products, the alloy composition is made by adding the alloying elements to molten aluminum, usually in the form of a concentrated master alloy (sometimes called hardener), with the requisite purity and composition (Hatch, 1984; Vasudevan and Doherty, 1989; Polmear, 1995). Two types of alloying elements are normally added: those for achieving strength through hardening mechanisms and those to control the grain structures during solidification (grain refiners) and deformation (anti-recrystallization agents), the former producing nucleating particles during solidification, the latter forming “dispersoids” upon annealing. During solidification of an ingot or a casting, some of the alloying elements and impurities may precipitate out of the melt, forming coarse “constituent” particles within the as-cast structure. These are usually formed through primary solidification, eutectic or peritectic reactions. For wrought products, additional precipitation of the alloying elements may occur as the ingot is annealed or worked down to the final product form (such as sheet or plate). These are usually much smaller dispersoids.

Some of constituent phases potentially impair the properties of the final product in several ways. (a) By tying up alloying elements that are added on purpose to develop the desired properties, these elements then become not available to contribute to strength and other beneficial properties of the aluminum alloy. (b) In addition, the constituent particles are typically more brittle than the surrounding aluminum and frequently possess elongated shape, hence, presenting stress concentrators in the structure and promoting the nucleation and growth of cracks, impairing the beneficial mechanical properties. One typical goal of aluminum alloy processing is to reduce the size and amount of the constituent particles in the aluminum alloy product, especially in wrought products. Note that in casting alloys, a significant portion of the alloys structure is occupied by the major eutectic structure constituent, e.g., Al-Si eutectics, that defines the casting properties of the alloys and, therefore, is an essential beneficial component of the structure (Glazoff et al., 2019). An example of such a structure is given in Fig. 1a that shows a modified Al-Si eutectic that defines the properties of these alloys.

Casting and especially wrought alloys are grain refined upon casting with the aim to achieve a uniform equiaxed grains (dendrites), which is important for the mechanical and technological properties upon casting and downstream processing, e.g., decreases hot and cold cracking, shortens homogenization, improves ductility upon hot deformation. A typical example of the grain refined structure of a DC cast billet from a 7075 alloy is shown in Fig. 1b. Casting is conventionally followed by a homogenization (or solution) treatment. This is the stage when nonequilibrium structure constituents (eutectics) dissolve and enrich the aluminum solid solutions with the alloying elements such as Cu, Si, Mg, Zn, Li whereas some of the elements (e.g., Zr, Ti, Mn, Cr, V, Sc) that have supersaturated aluminum during solidification precipitate as dispersoids (Hatch, 1984; Vasudevan and Doherty, 1989; Toropova et al., 1998). For alloys used in the as-cast condition and for non-age-hardenable alloys, homogenization may be the final heat treatment. But for age-hardenable alloys further heat treatments will be required. For wrought alloys, hot working follows the homogenization for ingot breakdown (rolling) and shape change (forging, extrusion) to the appropriate product form. Since aluminum and its alloys have high stacking-fault energy, sufficient dynamic recovery normally occurs during hot deformation to give rise to a stable polygonized substructure, an example of which is shown in Fig. 1c. The grains elongate in the direction of metal flow and do not recrystallize. The fine distribution of dispersoids associated with Cr, Mn, Zr, Sc additions delays or prevents static recrystallization by pinning down subgrain boundaries and stabilizing the polygonised structure, retaining the elongated or “pancake-shaped” grains during subsequent processing (Hatch, 1984; Vasudevan and Doherty, 1989; Davis, 1993). An example of the grain structure of a hot-worked aluminum-alloy plate is shown in Fig. 1d. The dispersoids, and any remaining constituents and primary phases that may be present, are strung out in the working direction; their spacing increases in the working direction and decreases normal to the working direction. In some cases, large constituent phases, if present, are broken up during the working operation. After the initial processing for shape change, non-age-hardenable alloys may then be cold worked and/or annealed to develop the desired strength, and age-hardenable or heat-treatable alloys may be solutionized (operation similar to homogenization but aimed at further increasing the concentration of useful alloying elements in the solid solution), quenched (fixation of the supersaturated solid solution at a lower temperature), in some cases stretched to remove residual stresses developed

Fig. 1 Typical microstructures formed in aluminum alloys: (a) an as-cast A357 alloy showing modified Al-Si eutectics (optical microscopy, OM); (b) a grain refined structure of an as-cast 7075 billet (OM); (c) subgrain (polygonized) structure formed upon hot rolling of an Al-Cu-Mg-Li-Zr alloy (transmission electron microscopy, TEM); and (d) a “pancake” grain structure formed upon hot deformation in the same alloy as (c) (OM).

Fig. 2 (a) Dark-field TEM micrograph of an Al-2.7% Cu-1.8% Li-0.6% Zn-0.3% Mg-0.3% Mn-0.12% Zr alloy quenched and naturally aged for 7 days. The matrix precipitation is dominated by fine coherent δ' (Al_2Li) spherical precipitates and (b) bright-field TEM micrograph of the same alloy quenched and artificially aged at 150 °C for 6 h (T6 temper). The matrix precipitation is dominated by fine θ''/θ' (Al_2Cu) plates and δ' spheres (not visible).

during quenching or for creating nucleation sites for precipitation, and either naturally aged at room temperature or artificially aged at some moderate temperatures (Hatch, 1984; Davis, 1993; Polmear, 1995). A structure of an Al-2.7% Cu-1.8% Li-0.6% Zn-0.3% Mg-0.3% Mn-0.12% Zr alloy naturally aged at room temperature after a rapid quench from the solution heat-treatment temperature is shown in Fig. 2a and the same alloy artificially aged at 150 °C for 6 h after a rapid quench from the solution heat-treatment temperature is shown in Fig. 2b. The main purpose of aging treatments is to precipitate fine, coherent or semi-coherent particles from the supersaturated solid solution, which will hinder the dislocation movement and, thereby, increase the strength of the alloy (Hatch, 1984; Totten et al., 2019).

Alloys that are prone to corrosion in moist air may be clad with pure aluminum, which is not susceptible to corrosion and can offer protection in an aggressive environment, or they may be anodized (Vasudevan and Doherty, 1989; Polmear, 1995; Totten et al., 2019). Cladding is typically done by joint hot rolling of the main alloy ingot with thinner layers of pure aluminum on top and

at the bottom. More recently a technology of joint direct-chill casting of clad ingot has been commercialized, making the bonding between the main alloy and the clad layer more reliable. Anodizing is a method for producing a very thick, protective oxide film on the surface of aluminum. The anodized film normally contains chemical compounds such as chromates, which are collected from the anodizing bath and render the film more corrosion resistant than films that form naturally in air.

Aluminum alloy design

After Wilm discovered age hardening of the Al–Cu–Mg–Mn alloy through serendipity, traditional aluminum alloy development primarily relied on a trial-and-error philosophy. The rapid acceleration of aluminum production in the first half of the 20th century was driven by the automotive and aircraft industries. If the former used aluminum in luxury cars, the latter utilized light weight and high specific strength of aluminum alloys for building mass produced airplanes, from engines to fuselage. At that time most aluminum alloys were developed by simply identifying a given alloying element that led to gains in a certain mechanical property, typically strength, and continuing to add that element until the property began to degrade. The amount of secondary element used would then be the percentage that corresponded with maximum performance. This process would then follow in ternary and higher-order systems in order to optimize a given mechanical property. Up until the 1940s only optical microscopes were available for structure examination, and phase diagrams availability and use were very limited. Therefore, the alloy design occurred with little knowledge of the corresponding microstructural components or appropriate thermodynamic understanding, for instance the phase diagram of the particular alloying system. Unfortunately, this practice led to the slow adoption of novel alloys into various applications creating a disparity with the design community. Yet main alloying systems used today, i.e., casting alloys of Al–Si–(Mg)–(Cu) system and wrought alloys of Al–Cu–(Mg), Al–Zn–(Cu)–Mg and Al–Mg–Si, have been developed prior to the 1940s (Mondolfo, 1976).

From the 1950s and progressively up to nowadays, the aluminum-based alloy development utilizes the knowledge of phase diagrams and the productive interplay between empirical research and theoretical science. Phase diagrams represent the phase state of an alloy as a function of temperature and alloy concentration (pressure is rarely an important factor in condensed systems) and are widely used for alloy design and process development (e.g., determining the temperatures of heat treatment). There are currently software programs (e.g., Thermocalc, Pandat, MTDATA) available that use thermodynamic functions and extensive databases for the calculation of multi-component phase diagrams and some physical properties. Such calculations reduce the effort required to determine equilibrium and nonequilibrium (these software packages allow one to take into account diffusion) conditions in a multicomponent system. Materials design can now be viewed as the best application of available models for the prediction and synthesis of alloys with desired properties. Nowadays, a combination of thermodynamic calculations, vast experimental data and artificial intelligence opens way for developing alloys that are far from traditional in composition, or for optimizing the existing grades for the best performance (Belov et al., 2005; Glazoff et al., 2019; Mishra and Thapliyal, 2021). Of course, all theoretical calculations must be verified experimentally, but these experiments can now be based on the sound theory and not on a trial-and-error approach.

The most general understanding of alloy design must derive itself from the metallurgical paradigm of processing–structure–property relationships (Polmear, 1995; Glazoff et al., 2019). In order to optimize a given property, one must determine the necessary ideal microstructural components, which are dictated by the alloy composition and processing from solidification through final manufacture. Fundamentally, to properly determine the resulting microstructure for a given thermomechanical processing routine, the pertinent literature and (non)equilibrium phase diagrams must be consulted. The basic empirical structure–property relationships found in aluminum alloys are summarized in Table 3. This table highlights the general structural features desired to optimize a given property.

Non-heat-treatable alloys

The 1XXX, 3XXX, 5XXX, and some of the 8XXX series alloys are non-heat-treatable, or rather non-age-hardenable (Mondolfo, 1976; Sanders et al., 1986; Davis, 1993). These alloys are primarily strengthened by the elements in solid solution, dispersoids and by deformation structures. One of the first non-heat-treatable alloys, other than the 1100 alloy that only contained 0.95 wt% Fe and Si as impurities, was an alloy containing 1.25 wt% Mn and 0.12 wt% Cu, now designated as 3003, that was introduced in 1906, the same year that Wilm discovered age hardening. Alloy 3003 can develop yield strength up to 400 MPa by special thermomechanical treatments that assure the non-recrystallized or fine recrystallized structure after deformation. Magnesium is added to non-heat-treatable alloys for its solid-solution strengthening effect. It also enhances work hardening and makes aluminum more anodic. In general, solid-solution alloys are more resistant to corrosion than two-phase alloys. Al–Mg alloys have a high resistance to corrosion, particularly in seawater and alkaline solutions. However, when the magnesium concentration exceeds the solid solubility in binary alloys, it precipitates at grain boundaries as Al_3Mg_2 , which is anodic to the matrix and promotes intergranular attack.

Aluminum combines readily with transition metals, such as Ti, V, Cr, Mn, Fe, Co, Ni, Zr, and Sc to form intermetallic phases with little or no solubility in the aluminum matrix at room temperature (but with a considerable tendency to form supersaturated solid solutions upon solidification) (Toropova et al., 1998; Belov et al., 2005). This supersaturated solid solution decomposes upon technological anneals or homogenization to form intermetallic phases (dispersoids) that increase the strength by enhancing work

Table 3 Property–microstructure relationships in aluminum alloys.

Property	Desired microstructural feature(s)	Function of feature(s)
Good casting properties	Large amount of eutectics or pure solid solution Narrow solidification range	Provides good fluidity and feeding, reduces cracking and porosity upon casting
Strength	Fine, uniform grains Fine grain size with a uniform dispersion of small, hard particles (dispersoids, precipitates)	Less stress accumulation, less segregation and cracking Inhibits dislocation motion, pins subgrain boundaries
Ductility and toughness	Fine structure with clean grain boundaries and no large or shearable precipitates	Encourages plasticity and work hardening, inhibits void formation and growth
Creep resistance	Slow diffusing alloying elements Thermally stable particles within the matrix and on the grain boundaries	Slows-down diffusion processes Inhibits grain boundary sliding and coarse microstructure
Fatigue crack initiation resistance	Fine grain size with no shearable particles and no surface defects No brittle inclusions and intermetallics with elongated/sharp morphology	Prevents strain localization, stress concentration, and surface slip steps
Fatigue crack propagation resistance	Large grain size with shearable particles and no anodic phases or hydrogen traps	Encourages crack closure, branching, deflection, and slip reversibility
Pitting corrosion	No anodic phases	Prevents preferential dissolution of second-phase particles
Stress corrosion cracking and hydrogen embrittlement	Hard particles and no anodic phases or interconnected hydrogen traps	Homogenizes slip and prevents crack propagation due to anodic dissolution of phases

hardening during working operations, and by refining the grain structure. They increase the work hardening since they are usually incoherent with the matrix (metastable Al_3Zr , Al_3Ti and equilibrium Al_3Sc are notable exceptions), are nondeformable, and must be looped or bypassed by moving dislocations. This increases the dislocation density and blocks the dynamic recovery and recrystallization processes (the temperature of the recrystallization onset may go up to the solidus temperature in the case of Sc in Al-Mg alloys). During hot working, the subgrain structure that is developed can also increase the strength. Smaller (less than $0.6\ \mu\text{m}$) intermetallic dispersoids aid in the stabilization of the substructure. The intermetallic particles generally do not add a component of the dispersion strengthening because of their low volume fraction, relatively large size, and interparticle spacing. The famous exception is Sc that when added alone (up to 0.3 wt%) or in combination with Zr (0.15 wt% each) to Al-Mg alloys can provide dispersion hardening due to the precipitation of coherent spherical Al_3Sc particles that retain coherency and size stability to high temperatures (Toropova et al., 1998). Such Al-Mg-Sc alloys attract a lot of attention in aerospace and automotive industries, and become effectively age-hardenable, though the aging temperatures are above typical, being in the range $250\ ^\circ\text{C}$ – $350\ ^\circ\text{C}$.

It is customary to control both composition and cooling rates in order to prevent large primary phases from forming. For example, commercial Al-Mn alloys most often contain less than 1.25 wt% Mn, although as much as 1.82 wt% is soluble in pure aluminum. The 1.25 wt% limit is imposed because Fe, present in most aluminum alloys as an impurity, decreases the solubility of Mn in aluminum. This increases the probability of forming large primary particles of Al_6Mn , which can have a disastrous effect on ductility.

Silicon is a principal addition to most aluminum casting alloys because it forms an Al-Si eutectic that increases the fluidity of the melt (Glazoff et al., 2019). In the solid state, hard silicon particles are the major contributor to the strength of non-heat-treatable casting alloys. An additional improvement in strength can be obtained by minor additions of Mg or by trace alloy additions, for example, Na or Sr that modify the eutectics. The latter also minimizes porosity and increases ductility.

Heat-treatable alloys

The 2XXX, 4XXX, 6XXX, 7XXX, and some 8XXX series wrought alloys as well as 2XX.X, 3XX.X and 7XX.X series casting alloys are considered heat-treatable (age-hardenable) (Hatch, 1984; Vasudevan and Doherty, 1989; Davis, 1993; Starke and Staley, 1996; Gokhale et al., 2013; Ovsyannikov et al., 2016). These alloys contain elements whose solubility in solid aluminum is substantial at high temperature and decreases with temperature, e.g., Cu, Zn, Mg + Si, Li. The concentration of these elements significantly exceeds their equilibrium solid solubility at room and moderately higher temperatures. One or several of the transition elements Cr, Mn, Zr, and Sc are typically added to age-hardenable wrought alloys to control the grain structure upon and after deformation; however, the grain and deformation structures play only a secondary role in the strengthening of this class of materials.

A normal heat-treatment cycle after deformation processing for wrought alloys (or after casting for casting alloys) includes a soak at a high temperature to dissolve the soluble constituent particles and any other precipitates that may be soluble (dispersoids containing the elements Cr, Mn, or Zr have already precipitated at this point). After the aluminum alloy has been held at the solutionizing temperature for a sufficient time, the alloy is rapidly cooled or quenched to prevent precipitation of coarse phases and

to obtain a solid solution supersaturated with both solute elements and vacancies. The next step involves aging at room temperature (natural aging) or at an intermediate temperature (artificial aging).

Quenching is accompanied by a change in free energy, which increases progressively as the difference between the solutionizing temperature and the final quenching temperature increases, which defines the difference in the equilibrium solubility and the supersaturation degree at the aging temperature (Hatch, 1984; Polmear, 1995). The volume free energy change representing this difference is the driving force for precipitation and is associated with the transfer of solute atoms to a more stable phase. However, when precipitation occurs there are other factors that increase the free energy, e.g., the formation of the interface between the matrix and the precipitate requires an increase in the surface free energy; and, if there is a volume change or interfacial strains associated with the precipitate (i.e., due to the coherent or semi-coherent nature of the interface), there is an increase in the elastic strain energy. The change in free energy when a precipitate forms, ΔG , is the sum of these free energy changes and can be expressed mathematically as

$$\Delta G = V\Delta G_v + A\gamma + V\Delta G_s \quad (1)$$

where V is the volume of the new phase; ΔG_v is the free energy decrease due to creation of a volume, V , of the precipitates and is therefore negative; A is the area of the interface between the matrix and the precipitate; γ the energy of the new surface formed; and $V\Delta G_s$ is the increase in elastic strain energy per unit volume of precipitate.

The critical increase in the free energy, ΔG^* , required for a nucleus to become an equilibrium or metastable precipitate is known as the activation energy barrier for nucleation and can be expressed as

$$\Delta G^* = (16\pi\gamma^3)/(3[\Delta G_v - \Delta G_s^2]) \quad (2)$$

The nucleation rate, N , can be expressed as

$$N = C \exp\left(-\frac{Q}{kT}\right) \exp\left(-\frac{\Delta G^*}{kT}\right) \quad (3)$$

where C is the number of nucleating sites per unit volume, Q is the activation energy for diffusion, k is the Boltzmann constant, and T the absolute temperature.

The precipitates typically go through a number of morphological transformations: starting with the formation of atomic clusters (GP zones), followed by the formation of a series of metastable phases that feature coherent and semi-coherent boundaries with the matrix, and eventually the formation of a stable phase. The GP zones and coherent precipitates are the main hardening agents upon natural aging, while coherent and semi-coherent precipitates harden alloys during artificial aging (Hatch, 1984; Totten et al., 2019).

There are a number of requirements for an effective age-hardenable alloy. First, there has to be a sufficient volume fraction of the hardening phase for the desired strength. An examination of aluminum binary diagrams suggests that the most attractive alloying additions would be, in decreasing volume fraction of the second phase, Ag, Mg, Li, Zn, and Cu. The required volume fraction will depend on the effectiveness of the second phase in impeding dislocation motion, that is, whether it is a "soft" or "hard" phase, and its size and spacing. Second, the aging potential must be adequate and the nucleation of the precipitates should be as close as possible to being homogeneous. This is generally accomplished by the addition of a second alloying element. The addition of the second alloying element may: (1) reduce the solubility of the first element, (2) increase the diffusion rates by trapping vacancies, (3) increase the driving force for nucleation, or (4) reduce the activation energy against nucleation. If the strain term in Eq. (1) is large, nucleation may be aided by defects, for example, dislocations. For this type of nucleation, the precipitate distribution depends on the distribution of the defects.

The stability of the aging effect depends on the stability (growth rate) of the hardening precipitates that is mainly dependent on the diffusion rate of the contributing elements.

Alloys for additive manufacturing

Specialized alloy development for additive manufacturing (AM) is still a young field with most of AM alloys being based on conventional casting or wrought alloys with small variations in chemical composition. Light alloys, especially Al-based, has attracted strong attention in additive manufacturing due to the promise of a high specific strength, yet this is hindered upon AM due to the high thermal expansion/contraction of aluminum alloys, which results in cracking, distortion and segregation, deteriorating the service performance. Alloy development is currently based on near-eutectic Al-Si-(Mg)-(Mn) alloys due to their good casting properties (but average strength) or alloys with transition metals stemming from rapidly-solidified alloys with good thermal stability (but poor casting performance) (Aboukhair et al., 2019; Aversa et al., 2019; Martin et al., 2017; Mishra and Thapliyal, 2021; Thapliyal et al., 2021). Both groups have deficiencies that are partially mitigated through operating in a tiny processing window, which is often not transferrable between machines (even of the same model), requiring costly optimization. On the other hand, AM provides novel opportunities for alloy development that is currently guided by thermodynamic calculations to alter alloys through nano-additives or a combination of low-diffusing elements, achieving a new level or new combination of properties and quality. This requires targeted material development intimately linked to specific alloy characteristics, processing, and characterization.

The heating and cooling rates upon AM are up to five orders of magnitude faster than in conventional processing, causing AM components to have non-optimal microstructure, mechanical properties and dimension accuracy due to the formation of defects such as porosity, epitaxial columnar grains, distortion and cracking, lack of nucleation control, residual stresses and thermal contraction. This poor service performance imposes barriers for Al-10 wt% Si-based as well as 2XXX-, 6XXX- and 7XXX-series alloys to be suitable materials for AM. Recently, some Al-based alloys have been specifically designed for AM, mostly exploiting earlier developments in rapid solidification (RS) and dispersion hardening. This includes alloys with transition metals, e.g., Sc and Zr (Scalmalloy, Addalloy) with good service performance such as thermal stability and strength, though still inadequate process performance. Achieving high-quality AM parts with bespoke, thermally stable properties requires the control of composition, structure and processing on the nano- and micro-level. For example, small additions of Zr nanoparticles can help in avoiding cracking of AM 6XXX- and 7XXX-series alloys through grain refining, thereby achieving adequate mechanical properties (Martin et al., 2017). Completely new alloys with a high amount of transition metals (Al₂₀Si₅Fe₃Cu, Al₈₅Nd₈Ni₅Co₂, Al₇NiZnMg) are under development (Plotkowski et al., 2020).

Microstructural features

Chemical composition and processing regime control the microstructure and thus the physical, mechanical, and corrosion properties of aluminum alloy products. In general, microstructural features of importance for property control include the following (Hatch, 1984; Vasudevan and Doherty, 1989):

1. *Coherency, volume fraction, and distribution of strengthening precipitates.* These form intentionally during aging treatments and unintentionally during cooling, including quenching. The precipitates normally range in size from 1 to 10 nm.
2. *Size, distribution, and coherency of dispersoid particles.* These form during the ingot preheating or homogenization treatment by precipitation of the transition elements Cr, Mn, Ti, Zr, Sc. They are present by design to control the grain structure and degree of recrystallization. Dispersoids normally range in size from 10 to 200 nm.
3. *Degree of recrystallization.* This is determined by the thermomechanical history. During bulk metal deformation processing at elevated temperatures, the dislocations in aluminum alloy products arrange themselves into a structure of small-angle sub-boundaries by the process known as dynamic recovery. As temperature decreases and strain rate increases, the stored energy increases. This increase in stored energy is manifested by an increase in number and consequent decrease in the size of subgrains and an increase in the dislocation density in cell walls. During subsequent heat treatments, the stored energy of deformation may decrease by either static recovery or recrystallization. The final product may be completely unrecrystallized (cold worked), partially recrystallized (polygonised), or completely recrystallized.
4. *Grain size and shape.* In casting alloys, the grain size, dendrite arm spacing and fineness of eutectics are paramount factors for the performance and properties. In the wrought alloys, the grain size and shape are controlled by thermomechanical history and may be influenced by ingot grain refining practice.
5. *Crystallographic texture* (i.e., preferential crystallographic orientation of grains). The deformation process used to produce the product and the thermo-mechanical history determines this.
6. *Intermetallic constituent particles.* These form mostly by eutectic reactions during solidification, primarily from impurities, for example, iron and silicon. Because the low solubility of iron in pure aluminum is further reduced by alloying elements, constituent particles containing iron are virtually insoluble. Other constituent particles, e.g., Al₃Zr, can be primary intermetallics formed in peritectic systems. The amount, size and size distribution of insoluble constituent particles are controlled by the alloy composition (purity), cooling rate upon solidification, and the extent and nature of bulk deformation. Constituents generally range in size from 1 to 30 μm .
7. Porosity may be a factor in thick plates and, particularly, in castings. It is controlled by the amount of hydrogen that is retained in the liquid or solid aluminum. Individual pores can range up to and beyond 200 μm .

Applications of aluminum alloys

Aluminum alloys are lightweight, resistant to atmospheric corrosion, and have good mechanical properties (especially if their low density is taken into account), which makes them a popular material for use in a wide variety of applications. The first mass applications of aluminum alloys were in automobiles and airplanes (Altenpohl, 1998; Polmear, 1995; Starke and Staley, 1996). They remain materials of choice in aerospace applications and, increasingly, in modern personal and transport vehicles, driven by the need for light weight to limit the emissions, increase fuel efficiency, and enable longer range for electric cars. Other applications are also very important (Menzie et al., 2010): packaging, building structures, marine applications, electric conductors, to name a few. In total about 41% of global aluminum production is consumed by foil and packaging; 22% by transport; 11% by construction; 13% by electric engineering; 8% by machine engineering; and 5% by consumer goods.

The 1XXX alloys are strain-hardenable and not toxic, have high formability, corrosion resistance, and good electrical conductivity. They are often used for electrical applications and as foil and strip for packaging. The 2XXX alloys are heat-treatable, and possess excellent combinations of high strength and toughness even at elevated temperatures, but are not resistant to atmospheric corrosion; so, they are usually painted or clad in such exposures. They are primarily used for aircraft frames, truck body applications, and cryogenic propellant tanks. The 3XXX alloys have high formability, corrosion resistance, and can be joined by a variety of

methods. They are widely used in cooking utensils, beverage cans, food containers, chemical equipment, roofing and siding, and in heat exchangers. The 4XXX alloys are heat-treatable and have good casting characteristics along with medium strength. They are primarily used in forging applications, for example, engine pistons, and for welding wires. The 5XXX alloys are strain-hardenable, tough and weldable, and have excellent corrosion resistance, even in salt water, along with moderate strength. They find wide application in highway bridges, storage tanks, marine and automotive structures, and pressure vessels. The 6XXX alloys are heat-treatable, have high corrosion resistance, excellent extrudability, and moderate strength. They are primarily used in building and construction, automotive, marine and aerospace applications. The 7XXX alloys are heat-treatable and can provide the highest strengths of all aluminum alloys. They are primarily used for automotive and aerospace applications. The 8XXX series is used for alloys that contain lesser-used alloying elements such as nickel and lithium. Some are used for electrical conductors and the lithium-containing alloys have found application in the aerospace industry due to the lithium effect in reducing density and increasing rigidity.

Aluminum casting alloys are used for engine blocks and pistons, heavy-duty structural parts in automotive and airplane applications, pumps, impellers, fittings etc.

Conclusion

Aluminum alloys possess a number of very attractive characteristics that, together with their light weight, make them extremely attractive for many applications. Since aluminum comprises 8% of the Earth crust by weight, the overall reserves are adequate to cope with anticipated demands for the foreseeable future. Cost differentials and carbon footprint with respect to competing materials will probably dictate the extent to which aluminum will be used. The cost includes the price of the electrical energy needed for the extraction of the metal from its minerals, and this may be greatly reduced in the future since aluminum can be fully recycled for many applications. In addition, aluminum often pays off when lifecycle costs, instead of acquisition costs, are considered.

Abstract

Superalloys are the materials of choice for high temperature structural applications, particularly within the aerospace industry. In this chapter, a brief overview of superalloys, their development, applications, physical metallurgy, and future considerations is included. Short case studies are used to highlight the drivers of superalloy design and the synergistic development of the field with manufacturing practices to achieve the required balance of properties for high temperature service. The chapter concludes with a brief section on future considerations, particularly on decarbonization and sustainability factors.

Key points

This chapter aims to equip the reader with:

- A historical context and trends driving the development of superalloys for key applications.
- An understanding of the role of alloy composition in delivering a desirable property balance for specific industrial applications.
- A brief summary of how superalloys obtain their unique high temperature strength and the mechanisms that drive the plastic deformation of this alloy class.
- A basic understanding for future industry demands of superalloys and what key challenges are associated with delivering green aeroengine concepts.
- Insights into principal challenges surrounding the sustainability of superalloy component manufacturing and securing the necessary raw materials.

Introduction

Metallurgical and materials advances have come to define human history by enabling transformative technological developments. Superalloys are no exception, being synonymous with the jet age. While it is difficult to provide an exact definition of superalloys, Sims, Stoloff and Hagel (Sims et al., 1987) define superalloys as "...alloys based on Group VIIIA-base elements developed for elevated-temperature service, which demonstrate combined mechanical strength and surface stability." It is indeed their combination of properties, ranging from strength to fatigue and environmental resistance, and damage tolerance, derived from their unique microstructures, that has seen superalloys deployed widely in a number of applications across the aerospace and energy generation sectors. This is particularly the case where temperatures in excess of 700 °C are encountered in service, i.e. at a temperature beyond the stability of steels.

Superalloys were first discovered in the late 1920s when small amounts of Al and Ti were added to the well-known 80/20 Ni-Cr alloy, resulting in significant strengthening, and marked improvements in creep performance compared to the ferritic steels used then in high strength - high temperature applications. Although not rationalized until years later in the 1950s, the additions of Al and Ti resulted in the precipitation of the γ' phase, from which superalloys derive their exceptional mechanical properties. The continuous development of jet engine technologies, coupled with the immediate need for strong but also cost efficient and reliable materials during World War II, led to a clear demand for new materials in jet engine applications. Consequently, over the 1950s and 1960s, superalloys experienced increased usage along with concentrated efforts on compositional design to advance the jet age. Since then, a continual drive for efficiency improvements within the power generation industries, and particularly within the aviation sector, has led to remarkable developments in manufacturing technologies, enabling ever more complicated alloy compositions and components to be realized.

Fig. 1 utilizes data presented by Sims in 1984 (Sims, 1984) and additional literature (refer to Tables 1 and 2 for reference list) to illustrate a timeline of superalloy chemistry development as charted through the primary companies and regions relevant to the

Fig. 1 Overview of key superalloy development ordered by time of development and sorted by alloy families and regions of development. Data taken from Sims (1984), Sims et al. (1987), Reed (2006), Naze et al. (2021), Keefe et al. (1992), Powell et al. (2016), Guédou et al. (1993), Guédou et al. (2008b), Hardy et al. (2004), Hardy et al. (2020), Ning et al. (2010), Radavich and Furrer (2004), Reynolds (2010), and Mourer and Bain (2013).

field. It is clear that the need for improved gas turbine technologies has been the primary driver for the advancement of superalloy chemistry design. However, in addition to their remarkable combination of properties at high temperatures, superalloys also exhibit exceptional performance in oxidizing and corrosive environments. This has led to them becoming ubiquitous in applications within highly corrosive environments, particularly within the power generation industries.

Classification and key phases in superalloys

As the definition put forward by Sims et al. (1987) suggests, superalloys are based on Group VIIIA-base elements and can be classed in three categories: Ni-Fe-based, Co-based, and Ni-based, depending on the concentration of the base element in the material and the key strengthening mechanisms utilized. The following sections present a brief introduction into the three key classifications of superalloys along with details of the phases present, applicable strengthening mechanisms and discussion of their historical development. For a comprehensive list of superalloy compositions the reader is referred to the seminal book by Reed (2006) or to the work of Reed and Rae (2014).

Ni-Fe-based superalloys

Ni-Fe based superalloys represent a natural progression from austenitic stainless steels. Using significant concentrations of both Ni and Fe, they are classified as a distinct category of alloys strengthened either primarily through solid solution modifications or precipitation hardening derived from both ordered and carbide phases. Ni-Fe-based superalloys are the most widely used class of superalloys due to their versatility at an approachable cost level. They are used across a broad range of sectors where both mechanical and environmental performance (particularly corrosion resistance) are paramount but where the service temperature does not usually exceed 700 °C. As an example, the most popular superalloy of all time, Inconel 718 (IN718), finds uses in a variety of industries ranging from the aerospace, marine, automotive, nuclear and petrochemical sectors, to cryogenic tanks for superconducting magnets, while remaining of great significance in jet engines where its usage often continues to exceed 50% by weight (Schafrik and Sprague, 2008).

Solid solution strengthened Ni-Fe based alloys are characterized by additions of Cr, Mo and W. In a study by Roth et al. (1997), Mo and W were found to be particularly potent solid solution strengtheners, calculated to offer ~1015 and 977 MPa at.%^{-1/2} strengthening improvements respectively. In addition to the solid solution strengthening afforded by additions of Mo and W, both elements are also known to have significantly lower diffusivities compared to most elements within the matrix, enabling improvements in the creep performance of the material. In contrast, while Cr additions enable improvements in oxidation and corrosion performance through the formation of protective and continuous Cr₂O₃ scales, the solid solution potency of the element is only 337 MPa at.%^{-1/2}. However, the increased solubility of Cr within the face centered cubic (FCC) γ matrix enables considerably higher additions of the element to be utilized. Furthermore, Cr, Mo and W are potent formers of topologically closed packed phases, such as the σ , μ and Laves phases, that cause the deterioration of the mechanical performance of the material, particularly under creep conditions (Wilson, 2016).

Fig. 2 Relationship between structures of carbides and the positions of metals in the Periodic Table (after Goldschmidt). Taken from Jena AK and Chaturvedi MC (1984) The role of alloying elements in the design of nickel-base superalloys. *Journal of Materials Science* 19: 3121–3139. <https://doi.org/10.1007/BF00549796>.

Carbide strengthening may further enhance the mechanical performance of Ni-Fe-based superalloys, via not only direct hardening, but also through the grain boundary pinning effects of carbide particles resulting in grain refinement and modifications to the recrystallisation behavior of the material. The most prominent carbide species observed in Ni-Fe-based superalloys are MC-type B1 (Strukturbericht notation) FCC monocarbides, where M may be Nb, Ti, Ta or Hf, or a mixture thereof, depending on the alloy composition - as shown in Fig. 2. Controlling the morphology of MC carbides to small globular particles at grain boundaries imparts the greatest benefits for strength and helps avoid grain boundary sliding during creep degradation as well as conveying damage tolerance. However, the formation of MC films along grain boundaries, often observed when inappropriate processing conditions have been chosen, results in embrittlement. Furthermore, destabilization of the MC carbides may occur, assisted by excessive additions of Mo and W, and leads to the formation of the non-cubic M_6C and $M_{23}C_6$ carbides, Fig. 2, with often deleterious effects on mechanical performance particularly if irregular morphologies are encountered.

In addition to solid solution and carbide strengthened Ni-Fe-based superalloys, intermetallic precipitation hardening is often utilized to further improve the mechanical properties of these materials. Additions of Al lead to the coherent formation of the ordered cubic Ni_3Al - $L1_2$ phase referred to as the γ' phase, Fig. 3. Where substantial concentrations of Nb are used at low Al:Nb ratios, the coherent and ordered tetragonal γ'' Ni_3Nb phase forms, Fig. 3. The coherent and ordered nature of the γ' and γ'' phases gives rise to appreciable strengthening within the alloys, which can be further tailored through control of the volume fraction, precipitate size, lattice misfit as well as fault energies of the precipitates. While both precipitates offer substantial strengthening benefits, the γ'' phase is by nature metastable and prolonged exposures at temperatures above 650 °C cause the transformation of the phase to the orthorhombic $D0_4$ δ - Ni_3Nb phase, which often tends to precipitate in a lath or needle like morphology, leading to embrittlement of the material. Consequently, particularly for applications where high temperature performance is critical, the γ' phase has been the dominant precipitation strengthening phase and is almost entirely utilized in the strengthening of Ni-based superalloys. Thus, the majority of the discussion within this review is focused on γ' strengthened superalloys.

Fig. 3 Chemical element arrangement in the crystal structures of the gamma-matrix (FCC-A1), gamma-prime ($L1_2$) and gamma-double prime ($D0_{22}$) phases that are key for precipitate strength.

Ni-based superalloys

Before charting the key development phases in the design of Ni-based superalloys, it is worth highlighting the fundamental characteristics that make Ni a suitable element for high temperature applications.

High temperature service necessitates materials that exhibit a combination of high strength, creep, fatigue and environmental resistance, favorable thermal expansion coefficient, to avoid in-service geometrical incompatibilities; as well as reduced density and cost. In addition, due to the prolonged high temperature exposure of these materials, a further requirement of microstructural stability is required so that the mechanical performance can be maintained during service for prolonged periods at high temperatures. With these considerations in mind, Ni forms an ideal base for high-temperature alloys. Firstly, with the exception of Cu, it is the only non-platinum group metal that adopts an FCC crystal structure, which remains stable at all temperatures, thus providing an inherent toughness and ductility to materials derived from it. Secondly, Ni exhibits a remarkable tolerance for alloying due to the fact that its third electron shell is nearly filled, hence, forming fewer chemical compounds that lead to intermetallic phases, which may degrade mechanical performance. Thirdly, Ni intrinsically displays low rates of self-diffusion, providing improved resistance against creep degradation.

As previously stated, Ni-based superalloys derive their strength primarily through precipitation hardening from the formation of the coherent, ordered, γ' -Ni₃Al phase. The historical evolution of Ni-based superalloys has focused on the compositional development of the alloys to account for demanding environments, while also utilizing advances in manufacturing to create a holistic approach toward microstructural design. Building on cast and wrought Ni-Fe-based alloys and austenitic stainless steels, the mechanical performance of Ni-based superalloys was initially improved through a reduction in the concentration of Fe in favor of increased Ni and Co concentrations, coupled with an increase in the concentrations of Al and Ti to promote the formation of the γ' phase. Due to the tolerance that Ni has for alloying, ever increasing numbers of elements have been used to tailor the performance of Ni-based superalloys further. Solid solution strengthening using Mo and W, as with Ni-Fe-based superalloys, continues to be utilized in Ni-based superalloys. Cr and Co, albeit less potent solid solution strengtheners than Mo and W, also feature prominently. Cr and Co exhibit high solubilities within the FCC Ni-based matrix, while also providing alternative benefits e.g. improved environmental resistance through Cr₂O₃ formation for Cr additions, or a pronounced reduction in stacking fault energy from Co additions that reduce the dislocation cross-slip potential of the alloy thus allowing for improvements in the creep performance of the material. Elements such as Al, Ti, Ta, Nb and Hf are also commonly found in Ni-based superalloys for the optimization of the γ' phase. For example, increased concentrations of these elements lead to an increase in the γ' volume fraction, modification of the anti-phase boundary energy and thus the order strengthening of the phase, as well as modifications of the γ/γ' lattice misfit and therefore the morphology and coarsening kinetics of the γ' phase, which may further influence mechanical performance. Additions of C, B and Zr are also frequently included for polycrystalline compositions and have been tailored over the years to optimize grain boundary strengthening and carbide/boride formation potential.

While the themes that have dominated compositional development in superalloys commonly include mechanical performance at high temperatures, the competitive advantage that can be derived by original equipment manufacturers (OEMs) from utilizing their own alloy compositions and defined manufacturing processes has led to a number of alloy development programs over the years to create bespoke alloys for key gas turbine components. A brief outline of key case studies that highlight the evolution of superalloy compositions and manufacture, is included below.

Alloys for turbine blades

The design of alloys for turbine blades, presents an exceptional case study in the synergistic development of alloy composition and manufacturing technologies to facilitate the increased temperature capability of these components. Turbine blades were initially produced in a wrought form with alloys such as the Nimonic series (80, 80A, 90, 105 and 115), IN100, and Udimet 700, i.e. alloys utilizing few alloying elements and relatively modest γ' fractions. The improvements in casting technologies facilitated the development of alloys with increased γ' concentrations as well as the introduction of simple cooling channel architectures within turbine blade components. Consequently, the compositions of the alloys could be developed to include a higher number of alloying elements, in particular higher concentrations of segregation prone solid solution strengthening elements, γ' forming elements as well as higher levels of C, B and Zr. The development of investment casting to allow for cooling channels to be included in the blade design further served to moderately allow for turbine entry temperatures higher than the temperature capabilities of the material as the cooling employed could provide an effective reduction in the service temperature experienced by the component. Further developments in the manufacturing technologies led to the introduction of the Bridgman process that facilitated the casting of directionally solidified (DS) alloys, with a reduced susceptibility to Coble creep, resulting in overall improved creep performance. Following on from the success of the Bridgman process, the addition of a single crystal seed or grain selector with a diameter smaller than the grain size, led to the momentous ability to cast turbine blade components in single crystal configurations, thus eliminating grain boundaries and minimizing creep degradation.

Since the advent of single crystal castings in the 1980s, the compositions of turbine blade alloys have evolved to optimize their resistance to creep deformation. As a result, most single crystal turbine blade compositions now utilize ~70% by volume of the γ' phase, with very high additions of Al and increased concentrations of Ta in favor of Ti. This allows for strengthening of the γ' phase, while also increasing the strength of the γ phase through solid solution strengthening and reducing the propensity to form freckle defects. Solid solution strengthening has also been of great interest due to both the strength benefits it offers, but more importantly the reduced diffusion through the γ matrix providing improved creep performance. Such is the importance of creep strengthening in

turbine blade materials, that the use of increased levels of refractory elements is now widely implemented and Mo, W, Re and Ru are the key elements used in single crystal superalloys for creep strengthening. However, their concentrations need to be judiciously reviewed as these elements also increase the propensity of the alloy toward TCP phase formation, particularly when increased levels of Cr are included, while simultaneously increasing the raw cost of the material. The addition of Cr may appear superfluous, given the propensity for turbine blade alloys to form a protective Al_2O_3 scale, but the addition of Cr is known to accelerate Al_2O_3 formation and so aid in environmental performance. It is thus a critical element within turbine blade compositions. Table 1, shows several of the relevant turbine blade alloys discussed herein, offering insights into compositional development.

In parallel to compositional modifications of single crystal alloys, advances in coating technologies also enabled further increases in the turbine entry temperature as sufficient insulation of turbine blade components could be achieved, while also providing improved environmental resistance for the material. As coatings became more common for turbine blades, it became a key design criterion to optimize for coating compatibility and cohesion with the blade substrate during service operation.

Exploring the development of turbine blade materials through the lens of the people and places that have contributed to their evolution provides interesting insights, Table 1. The early years of turbine blade alloys were dominated by material manufacturers, particularly Special Metals through their Nimonic and Udimet series, and INCO through the Inconel alloy family, Fig. 1. Through the 1960s and the equiaxed casting phase for turbine blade materials, Martin-Marietta Materials introduced the ever-popular Mar-M002, Mar-M200 and Mar-M247 alloys, whereas OEMs, starting with General Electric (GE), also entered the alloy design landscape. Pratt & Whitney (P&W) pioneered directional solidification but opted to use Mar-M200, which was later modified with Hf additions, leading to the derivative PWA 1422 alloy (Quigg, 1993). The advent of single crystal casting methodologies saw the increased involvement of OEMs in alloy design, with all major jet-engine manufacturers (GE, P&W and Rolls-Royce) investing in alloy development programs, resulting in the introduction of several René alloys from GE, SRR99 and RR2000 from Rolls-Royce (RR), and several PWA iterations from P&W (Quigg, 1993). In France, most key alloys were developed under the lead of ONERA, like the AM and MC alloy series, with a recent exception of the alloy Tropea developed by Safran and PPrime. However, more recently, the OEM boon in alloy design has receded, and the market leader to this day is Cannon-Muskegon (CM) a materials company that recognized a gap in the market for smaller OEMs not able to develop their own alloys (Wahl and Harris, n.d.). Responding to market demand, CM released a range of single crystal and DS alloys. CMSX-4, one of the flagship CM single crystal alloys, has seen increased adoption by a number of companies across industrial sectors utilizing gas turbines. Such is the dominance of CMSX-4, that it appears in nearly a third of all publications on single crystal superalloys since its introduction.

In recent years, increased efforts for the design of novel turbine blade materials, particularly single crystal alloys, have been prominent in Japan and China. Through the Japanese National Institute for Materials Science, the TMS alloy series was established, aimed at progressively improving the creep performance of single crystal alloys through judicious compositional design (Koizumi et al., 2004). Careful, systematic studies of the effect of several elements on the mechanical performance of these materials led to hundreds of compositions, and six “generations” of superalloys, culminating with the sixth generation TMS-238 alloy. TMS-238 was designed to have mechanical performance similar to TMS-196, but with notably improved oxidation and hot-corrosion resistance, recognizing the increased importance of environmental resistance in ensuring the longevity of single crystal components in service (Kawagishi et al., 2012). However, the cost of the TMS alloy series is markedly higher than any other single crystal superalloy family, owing to the increased utilization of refractory and platinum group metals to achieve the impressive levels of creep resistance observed in these compositions, Fig. 4. In contrast to Japan, where alloy design efforts were concentrated to a single research institution, Chinese interest in turbine blade superalloy compositions has been varied and widespread, with a steady increase in interest starting from c. 2009 with ~60 documents with Chinese affiliations. This has culminated in nearly 600 documents in 2022 alone. While the majority of the work reported has focused on understanding existing alloys or ones with simple modifications (e.g. DD3), more recently, unique compositions have also been reported such as DD6 and DD9.

The critical relationships between strength, creep and cost for turbine blade alloys is highlighted in Fig. 4, where the tensile yield strength at 650 °C and creep rupture life at 1100 °C and 140 MPa are plotted for a number of key alloys mentioned above. The size of the bubble for each alloy corresponds to its average element price per tonne (specified in USD for averaged price data between 2016 and 2018). Looking at Fig. 4, the reader can find the superalloy CMSX-4 in the center of the graph, displaying an excellent trade-off between creep resistance, yield strength and price. Based on Fig. 4, the more recently developed superalloys, DD9 and Rene N6, provide a substantial improvement in creep life (noting that the x-axis is logarithmic) while maintaining comparable levels of yield strength and price. Meanwhile, the commercial alloys TMS-196 and TMS-238 offer a remarkable improvement in creep life, with a lower yield strength, but at a 12.5 fold increase in price per ton compared to CMSX-4. Provided the turbine gas temperature continues to rise in future engines, new alloys are expected to be developed to meet this demand, most likely occupying the development space highlighted in gray in the top right corner, while trying to minimize any further increases in price. Furthermore, the compatibility with coating technologies is expected to be an ever more important criterion, particularly with the changing temperature profiles and fuels expected of newer generation propulsion systems (Naze et al., 2021).

Alloys for turbine disks

Alloys developed for turbine disks offer a second case study that further demonstrates the synergistic development of compositional modifications, coupled with manufacturing improvements, to deliver critical components with enhanced service performance. The ever-increasing need for higher turbine entry temperatures, required for improved jet engine efficiency, sparked the boom in development for turbine blade materials. However, innovation in turbine blade technologies alone is inadequate if not complemented by developments in the turbine disks housing the blades. The design of materials for turbine disk technologies is further

Fig. 4 Static properties (creep at 1100 °C and 140 MPa and yield strength at 650 °C in MPa) plotted for selected Ni-based single crystal superalloys. The size of the bubble of each alloy represents its specific alloy price in USD per ton. The element prices were extracted from the US National Mining Information Centre of the United States Geological Survey [see <https://www.usgs.gov/centers/national-minerals-information-center>]. Property data used in this figure courtesy of Mansoz B PhD thesis, Université de Toulouse, France, 2023, Florence Pettinari-Sturm and Jonathan Cormier.

complicated by their size and operating environment, resulting in conflicting mechanical properties required at the bore and rim of the component, which a single material must be able to meet. For example, the rim of the component operates at a higher temperature compared to the bore, thus necessitating improved creep performance. In contrast, the bore of the component is much cooler, but experiences higher stresses due to both the rotational speed and combined weight of the turbine blades and the component itself, thus, necessitating good strength. Historically, the most popular alloys used for turbine disks have been the cast and wrought IN718, Waspaloy and Udimet 720Li alloys, utilizing increasing fractions of the γ' phase for improved mechanical performance, see compositions in Table 2. However, with Udimet 720Li, a γ' fraction and compositional complexity limit was reached for alloys to be able to be reliably manufactured using cast and wrought methods. Therefore, alternative manufacturing routes were sought to be able to deliver the balance of mechanical performance required for turbine disks, while simultaneously providing improved manufacturing quality. Thus, the emergence of powder metallurgy (P/M) in the 1960s provided a viable alternative for turbine disk component processing, enabling components from highly alloyed compositions to be manufactured with reduced segregation, due to the rapid solidification of powder particles, while retaining forgeability.

In stark difference to turbine blade compositional design, which has now come to be dominated by a materials manufacturer (Cannon–Muskegon) rather than OEMs, the development of powder metallurgy compositions for turbine disk applications has been, and continues to be, entirely driven by the OEMs. This highlights the enormous perceived competitive advantage that may be garnered from improved turbine disk service performance.

Investigations into P/M superalloys were initiated in the 1960s and progressed throughout the 1970s, focusing on the key parts of the manufacturing route development, from the production of “clean” pre-alloyed powders, to the powder consolidation steps and thermomechanical processing (Gessinger and Bomford, 1974). Initial interest in P/M superalloys was driven in part by gas turbine OEMs necessitating the manufacture of compositions with increased concentrations of Cr for hot corrosion resistance, as opposed to the Cr lean alloys, developed for turbine blades. In parallel, the demonstration of oxide dispersion strengthened (ODS) aluminium materials, further invigorated the possibility of ODS-Ni-based alloys that could only be manufactured using P/M methods. Despite these drivers, the advances in cleaner cast and wrought technologies, as well as the impressive levels of compositional development of Ni-based superalloys that rendered ODS-Ni-based alloys unnecessary, meant that progress in P/M

superalloys did not gain momentum until much later in the 1970s and 1980s to address challenges in making carefully controlled polycrystalline Ni-based superalloys with γ' fractions in excess of 45%.

Alloys such as IN100, Waspaloy and Udimet 700 dominated the initial research on P/M development, aiming to understand the effect of the process on the alloy properties, in particular fatigue and crack growth (Gessinger and Bomford, 1974). By 1974, Pratt and Whitney and GE advanced to scale-up production of IN100 and Astroloy, and René 95 respectively. Using the lessons learned from introducing P/M superalloys into service, enabled the bespoke design of new alloy chemistries targeting damage tolerance. GE introduced René 88DT in 1988 (Krueger et al., 1990) and openly discussed the development program for the alloy in the Superalloys 1992 meeting (Krueger et al., 1992), emphasizing damage tolerance as a key criterion for the development of the material as well as using P/M René 95 properties to frame the design targets. It wasn't until nearly a decade later that Rolls-Royce introduced their first P/M superalloy, RR1000, owing to their continued successful use of Udimet 720Li. Notably, in a paper presented in the Superalloys 2004 meeting, the development program for RR1000 also highlighted the use of thermodynamic calculation software for the prediction of phase formation. Utilizing CALPHAD and New-PHACOMP methods limited the number of compositions experimentally tested, and hence the overall cost of the development program. The main aim in the design of RR1000 was to minimize the volume fraction of γ' required for strength so that the damage tolerance of the alloy could be maintained. The formation of carbides was considered vital for the alloy, which led to an increase in the concentration of Co and the introduction of Hf, compared to U720Li. Similarly, the formation of TCP phases was identified as an issue and was controlled through the concentrations of Al, Cr and Mo, informed by New-PHACOMP calculations (Hardy et al., 2004).

Following a very different approach for the development of their next iteration of turbine disk superalloys, GE and P&W, collaborated on the High Speed Civil Transport project initiated by NASA to develop their respective alloys (Huron et al., 2008; Mourer and Bain, 2013; Reynolds, 2010). Two iterations of the alloy matrix were performed, and the alloys produced for screening tests were manufactured following the conventional powder metallurgy route of powder consolidation, extrusion, isothermal forging and supersolvus heat treatment. The first stage of design was to optimize the concentrations of the grain boundary strengthening elements, B, C, Hf and Zr, before the bulk alloy composition could be defined (Huron et al., 2008). The initial design criteria for the alloy were improved creep resistance and time dependent crack growth resistance, for which the concentrations of Ta, Nb and W were varied in the first matrix of alloys, and a reduction in the γ' solvus temperature, which was reflected in changes in the Al:Ti ratio and the concentration of Co. Subsequently, two base compositions that reflected the results obtained from the screening tests were selected, and a further iteration of alloys was designed, aimed at optimizing the compositions of Nb, Ta, Ti and explored higher Co concentrations for lower γ' solvus temperatures (Huron et al., 2008). After the completion of the High Speed Civil Transport program, both GE and P&W independently continued their development efforts utilizing the knowledge acquired through the program. This led to the design of René 104 (also referred to as ME3) and ME501 (GE) and PRA48 (P&W) as referred to in the literature/patents. The compositions of these alloys are, as expected, remarkably similar, Table 2 (Huron et al., 2008; Reynolds, 2010; Mourer and Bain, 2013).

Similarly to most alloy development programs, Safran also opted for an iterative process, informed by prior knowledge from the existing alloy N18 and simple PHACOMP calculations. Their main approach was to develop a powder processed alloy with a γ' fraction between 40% and 50%. However, the major issue was the control of TCP phases, for which a lower Cr concentration was used compared to most wrought alloys. Alloy SMO43, or N19, was developed, but Guédou et al. (2008a) state that this is a base composition from which further iterations can be performed.

Following on from RR1000, the next iteration of P/M alloys from RR focused on achieving improved mechanical performance through the utilization of a higher number density of small γ' particles at a volume fraction up to 53%, while also maintaining a coarse grain size (i.e. not relying on grain refinement for strength) (Hardy et al., 2020). In order to achieve the γ' distribution specified, Al, Ti, Ta and Nb were controlled to be within the 12.65–13.15 at.% range. The trends observed in turbine disk alloy compositional development, Table 2, highlight an initial utilization of higher fractions of γ' forming elements (Al, Ti, Ta and Nb) that has now plateaued reflecting the emphasis on manufacturability as well as time dependent crack growth. Further to the optimization of the mechanical performance, careful control of Ti, Ta and Nb to achieve phase stability was also sought, particularly in avoiding the formation of the δ and η phases. Oxidation and corrosion resistance were also explicitly taken into consideration at the design stage, reflecting the more holistic approach toward alloy design for high temperature structural parts.

Away from the developments on P/M disk alloys in the US and Europe, China and Russia have also explored the use of P/M alloys. While little is known about the Russian P/M alloy development programs, the Russian P/M superalloy EP741NP has been investigated by Radavich and Furrer (2004) and is believed to have been designed for improved creep resistance and elevated temperature service rather than conventional yield strength. In contrast to the secrecy surrounding the Russian P/M programs, the Chinese FGH96 alloy developed in the 1990s (Tao et al., 2011) has been extensively studied and reported upon in the open literature, with a notable increase in reports starting in 2012 and peaking with 180 publications in 2022 alone, reflecting the sustained interest in the material, its manufacturability and properties.

Alloys for additive manufacture

The case studies on turbine blade and turbine disk materials serve to demonstrate the synergistic development of superalloy compositions and manufacturing methodologies. Manufacturing advancements have been of paramount importance in enabling superalloy components to be utilized in some of the most inimical environments known. Consequently, the advent of metal

additive manufacturing (AM) has been of particular interest to the superalloys community, recognizing the potential that AM has to enable a step-change in efficiency improvements due to increased geometrical freedom as well as an improved “buy-to-fly” ratio reducing waste.

Several methodologies for metal AM are now available commercially. However, the three most prominent methodologies for Ni-based superalloys are laser powder bed fusion (L-PBF), electron beam melting (EBM) and laser directed energy deposition (L-DED). The first two methodologies are often referred to as “powder bed” techniques, as the component is built layer by layer using a thin layer of powder, over which the energy source traces the required geometry to melt it, before a second powder layer is spread. In contrast to the powder bed method, directed energy deposition relies on the deposition of molten material to the required surface, i.e. powder is blown into the path of the laser directly, hence the method is also often referred to as “blown powder.” For further details on metal AM, the reader is referred to the book “Additive Manufacturing Technologies” by Gibson et al. (2021).

As with most developing manufacturing processes, the majority of the work on AM of superalloys involves the use of established and commercially available compositions. Owing to the complicated and very rapid solidification profiles encountered within AM, the most readily AM-amenable superalloys are those that are also highly weldable, i.e. mainly Ni-Fe-based solid solution strengthened alloys, alloys comprising γ' fractions below 30%, or indeed γ'' strengthened alloys, such as the most popular AM superalloys, IN718 and IN625. The majority of the work presented in the open literature revolves around optimization of process parameters as well as small compositional changes to achieve repeatable builds with desirable grain structures, unlocking the potential for localized microstructural control.

While some of the benefits of AM can be derived for components manufactured from readily weldable alloys, the impact of AM would be most pronounced for components operating at the highest temperatures, thus necessitating high γ' fraction alloys. Of the high γ' fraction superalloys, CM247LC has been the most widely studied in AM, albeit with limited success for L-PBF production routes due to the cracking susceptibility of the alloy, resulting in unacceptable mechanical performance. Though EBM of CM247LC and other high γ' superalloys is achievable, the technology has lagged behind in industrial uptake, due to difficulties in ensuring the integrity of internal cooling channels, as well as thermal management, that often results in undesirable microstructures. The acquisition of Arcam by GE Additive, however, has accelerated the innovation on EBM, stimulating the industrialization of the methodology (Ramsperger and Eichler, 2023).

Nevertheless, despite the promising results from EBM of high γ' fraction superalloys, L-PBF remains of great industrial importance. Thus, considerable research is underway to understand high γ' fraction superalloys and design alloys capable of operating at the highest temperatures with improved amenability to L-PBF. To date, the alloy design landscape has been dominated by OEMs, notably within the aerospace industry. However, little information has been shared in the open literature about the design methodologies and strategies utilized, although several patents can be readily accessed (Engeli et al., 2017). In addition to the efforts of OEMs, alloy manufacturers as well as academic institutions have also been actively involved in alloy design activities. Similarly to the later compositional iterations of alloys for turbine disk applications, the open literature suggests that the development of novel compositions amenable to L-PBF utilizes computational approaches to enable rapid screening and downselection of alloys for testing (Tang et al., 2021; Ghossoub et al., 2022a; Conduit et al., 2019; Sun et al., 2022). Conduit et al. (2019) proposed a probabilistic neural network approach, coupled with thermodynamic calculations, that led to the development of Alloy DLD, which showed promising properties when compared to the CM247LC and C263 alloys manufactured using L-PBF. Comparably, using the “Alloys-by-design” approach, Tang et al. (2021) and Ghossoub et al. (2022b) explored the composition space of Ni-based alloys to identify and screen superalloys for applications at temperatures in excess of 850 °C. As a result of the work by Oxford University in collaboration with Alloyed, the ABD-850 AM and ABD-900 AM alloys have been introduced as viable candidates and patented (Cruden and Nemeth, 2019). In addition, the commercial uptake of these compositions has been ensured through collaboration with Aubert and Duval for the manufacture and supply of metal powders. Continuing the trend of materials manufacturers, Carpenter Technology are also active in the development of bespoke alloys for additive manufacturing, both in terms of more traditional Ni-based compositions, as well as CoNi-based concepts (Zhou et al., 2020; Forsik et al., 2018). Further to the more traditional compositions explored for AM, the concepts of Co-based γ' -strengthened superalloys (see next section), high entropy superalloys (Yeh and Tsao, 2017), and oxide-dispersion-strengthened alloys (Smith et al., 2020) are also being considered as possible solutions to achieve high temperature performance, while simultaneously being amenable to L-PBF. Albeit still in its relative infancy, it is anticipated that over the next decade substantial compositional developments will be achieved to realize superalloys manufactured using AM methodologies, potentially ushering in a new era for superalloy design.

Co-based superalloys

Ni-based and Ni-Fe-based superalloys form the largest categories of superalloys by volume of consumption. However, the third family of superalloys, Co-based superalloys, is of historical importance, and the advent of γ' -strengthened Co-based superalloys offers considerable promise for the development of novel compositions, particularly with improved amenability to AM. The very first patents involving Co-based alloys, were filed in the early 1900s for alloys based on the Co-Cr binary and Co-Cr-W ternary systems. These systems formed the then popular Stellite alloys that were widely used in various applications, such as industrial machinery, hip replacements and cutlery (Sims et al., 1987). A variation of Stellite alloys based on the Co-Cr-Mo-C quaternary system, commonly referred to as Vitallium, was also used widely in dentures. Vitallium was soon identified as a suitable aerospace alloy with the slight modification of reduced C content. The modified Vitallium alloy formed the foundation of conventional

Co-based superalloys that flourished in turbine blade applications until the late 1950s. Strengthening in these conventional Co-based superalloys is derived primarily from the formation of carbides and through solid solution strengthening of the matrix. Elements such as Ta, W, Nb, Cr and Mo contribute to solid solution strengthening, but they can also combine with C to form complex carbides. Hence, the extent of the contributions of each of the mechanisms to the strength of the alloys depends on the alloying elements used and the carbon content of the alloy. In addition to the mechanisms utilized in Ni-Fe-based alloys, carbides in Co-based alloys may also form skeletal networks that support loads during mechanical stressing. The typical carbides that may form in Co-based alloys are the MC, M_6C , M_7C_3 and $M_{23}C_6$ species, in which M is the metallic conjugate of the compound. Generally, as with Ni-Fe-based superalloys, MC carbides are the most desirable due to their cubic structure that forms coherently with the Al matrix and may offer increased stability to higher temperatures. Precipitation of M_7C_3 and $M_{23}C_6$ is considered deleterious, not only due to crystallographic instability issues, but also due to the high Cr content that is consumed in the formation of these carbides, which may lead to reduced environmental resistance.

While conventional Co-based superalloys continue to be used in a variety of applications, particularly where hot corrosion and weldability are a concern, it is γ' strengthened Co-Al-W-based superalloys that have dominated the literature and interest since 2006, when the stable formation of the ternary $L1_2$ $Co_3(Al,W)$ phase in the Co-Al-W system was identified by Sato et al. (2006). While the bulk of the work has been focused on model higher order systems deriving from the Co-Al-W ternary, key activities have also focused on developing alloys for specific jet engine applications. Pollock et al. (2010) and Tsunekane et al. (2011) identified the potential of single crystal castings and claimed a 150 °C advantage over conventional Ni-based single crystal alloys. Additionally, the low segregation of elements during solidification suggested that the alloys may not be prone to instabilities, hence, large castings of these alloys may be achieved. The manufacture of Co-Al-W in single crystal form also allowed the creep behavior of these alloys to be determined and compared against equivalent Ni-based single crystal alloys (Titus et al., 2012; Eggeler et al., 2014, Titus et al., 2015; Eggeler et al., 2016).

While the initial work on Co-Al-W-based alloys focused on their capabilities as cast, single-crystal turbine blade components, the latter developmental years have instead explored the potential of these materials for polycrystalline applications manufactured through cast and wrought, powder metallurgy as well as additive manufacturing methodologies. Building on extensive studies of fundamental systems and through robust experimental testing to establish the effects of differing alloying additions, Neumeier et al. (2015) reported the development of novel wrought Co-Al-W-based superalloys with improved mechanical and oxidation performance, compared to commonly used cast and wrought Ni-based alloys. More recently, Carpenter Technology Corp., utilizing computational design tools derived from the improved understanding of the thermodynamics of Co-based alloys, have also developed a viable cast and wrought CoNi-based superalloy that utilizes both Cr_2O_3 and Al_2O_3 scales for high temperature oxidation resistance, further demonstrating the commercial interest in materials from this family (Forsik et al., 2018; Forsik et al., 2020). In parallel to the activities exploring cast and wrought compositions, Knop et al. (2014) and Yan et al. (2014) have also explored polycrystalline Co-based superalloys for turbine disk applications, manufactured by powder metallurgy. Although these did not show significant improvements over Ni-based alloys, they did demonstrate the potential for continued development in the field (Hardy et al., 2018). With increased interest for high temperature capable alloys amenable to additive manufacture, research into Co-Al-W-based alloys has also been of interest in the last 5 years. Indeed, following on from the successful demonstration from Carpenter Technology Corp. of a cast and wrought alloy, a collaboration between the company and researchers at the University of California Santa Barbara and Oak Ridge National Laboratories reported on the development of a defect resistant CoNi-based superalloy for AM applications. The resultant composition contained ~70% by volume of γ' precipitates but crucially, was found to be amenable to both electron beam melting and laser powder bed fusion manufacturing methodologies and was able to achieve yield strengths in excess of 1 GPa, while simultaneously retaining ductility levels of ~13% at room temperature (Murray et al., 2020; Pollock et al., 2020). The rapid development of commercially viable alloys from the Co-Al-W-system has highlighted the importance of accelerated alloy development methodologies that utilize both high throughput testing and advanced computational tools in realizing novel compositions, while enabling manufacturing compatibility to be integrated at the initial stages of compositional design.

However, despite the efforts of the community and several beneficial attributes of alloys based on the Co-Al-W system, several limitations still exist. The most notable limitation is the supply of Co, an element that is mined almost exclusively in the Democratic Republic of Congo (DRC) following often ethically questionable practices. Coupled with the increased usage of Co in batteries, the instability in the supply of the element is a critical concern and in the absence of appreciable and demonstrable benefits over Ni-based superalloys, the industrial use of Co-based alloys is likely to remain low.

Physical metallurgy

The performance of superalloys, primarily those strengthened by ordered γ' - $L1_2$ and γ'' - $D0_{22}$ intermetallics, stems from the configurations of the dislocation structures as well as the interactions of the dislocations with the precipitate distributions, planar faults and line defects arising in the precipitates. Furthermore, the compositional and microstructural complexity of superalloys results in intricate deformation mechanisms that change considerably depending on the conditions applied.

For example, Fig. 5, highlights the relative deformation differences in tensile tests of the single-crystal Ni-based superalloy CMSX-4 performed at 750 °C with strain rates changing from 10^{-2} s^{-1} to 10^{-6} s^{-1} . The results demonstrate that the yield strength of the alloy is not significantly influenced by the strain rate applied, whereas the ultimate tensile strength is appreciably affected

Fig. 5 Tensile stress-strain curves of CMSX-4 deformed at 750 °C at three different strain rates: 10^{-2} s^{-1} (the green curve), 10^{-4} s^{-1} (the red curve) and 10^{-6} s^{-1} (the blue curve). All samples were tested to failure, presented as stress vs. strain. (A) A TEM micrograph with two beam contrast, $g = (220)$ from a tensile specimen tested at a strain rate 10^{-4} s^{-1} , interrupted at 3.3% strain. (B) TEM micrograph with two beam contrast, $g = (220)$ from a tensile specimen tested at a strain rate 10^{-2} s^{-1} interrupted at 4.8% strain. (C–E) TEM micrographs with two beam contrast, $g = (200)$ from a tensile specimen tested at a strain rate 10^{-6} s^{-1} . (C) The deformation structure interrupted at 1.2% strain. (D) The deformation structure interrupted at 2.7% strain. (E) The deformation structure interrupted at 10.2% strain. Inset: an inverse pole figure showing the orientations of the three specimens tested to failure in relation to the [001] tensile direction. Image and caption reproduced with permission from Wang-Koh YM, Messe OMDM, Schwalbe CWM, *et al.* (2023) The effect of strain rate on the tensile deformation behavior of single crystal, Ni-based superalloys. *Metallurgical and Materials Transactions A* 54: 1456–1468. <https://doi.org/10.1007/s11661-023-07007-x>.

(Wang-Koh, 2018). The corresponding TEM micrographs shown in Fig. 5, illustrate the dislocation response observed at selected key deformation stages, highlighting the differing deformation characteristics that result simply as a function of strain rate.

The tensile test example highlights that the use of these alloys for critical components requires extensive certification testing. Common test conditions and types are summarized in the Metallic Materials Properties Development and Standardization handbook and include physical properties, static properties like tensile, compression yield, shear and ultimate strength as well as fatigue and creep properties.

While the example included in Fig. 5 demonstrates the complicated deformation mechanisms active in superalloys, the principles of deformation in superalloys fall outside the scope of this introductory chapter and the reader is referred to the extensive review work of Reed (2006) and Reed and Rae (2014). Nevertheless, a summary of the key strengthening mechanisms that may be operational in γ' -strengthened superalloys is included in Table 3. The key strengthening mechanisms in superalloys can usually be grouped into the following: intrinsic strength (i.e. Peierls-Nabarro), dislocation hardening (i.e. forest hardening), grain size hardening (i.e. Hall-Petch), solid solution hardening, precipitate and coherency hardening (via antiphase boundaries, stacking faults and interfacial pinning). Depending on the deformation regime the components exposed to these mechanisms require a specific combination of mechanisms to deliver the desired strength. Thus, most alloys are tailored in composition and processing for the specific environments they operate in.

Future industry demands and sustainability considerations

While superalloys continue to serve the materials requirements of several sectors, in particular the aerospace and energy generation sectors, the continual drive toward decarbonization [European Commission, Directorate-General for Mobility and Transport,

Table 3 Summary of strengthening mechanisms in superalloys.

<i>Mechanism</i>	<i>Notes</i>	<i>Key elements</i>	<i>Further reading</i>
Grain size refinement and strengthening	Just as with any class of metallic materials, the grain size offers an effective method through which improvements in strength may be achieved. Care must be taken to ensure balance of mechanical performance, particularly due to notable deterioration of creep life with decreasing grain size. C, B and Zr are used for grain boundary control, often utilizing carbide/boride formation.	C, B and Zr	Hall, 1951; Petch, 1953; Jena and Chaturvedi, 1984
Solid solution strengthening of the γ phase	Utilizing elements with atomic radii that differ to that of the major element, i.e. Ni, Fe or Co, such that the lattice distorts around the substitutional solute atom, creating a strain field that interacts with dislocations and impedes dislocation motion, resulting in an increase in the strength of the material. Interactions occur due to both the lattice misfit and the elastic modulus mismatch.	Co, Cr, Mo, W, Re, Ru	Roth et al., 1997; Fleischer, 1961; Fleischer, 1963
γ' precipitate fraction	Increasing fractions of the γ' phase result in an increase in the strength of the material at higher temperatures. Care must be taken to ensure balance of properties and manufacturability is maintained.	Al, Ti, Ta, Nb, Hf	Beardmore, 1969
γ' precipitate size	γ' precipitate size and the overall distribution of γ' particles has a strong effect on the dislocation interactions observed, which is further complicated by the fault energies of the phase, resulting in plastic deformation regimes dominated by weakly coupled dislocations (for small precipitate sizes and large precipitate separation), strongly coupled dislocations (small precipitate separation, larger size) or Orowan looping (very large and/or incoherent precipitates).	Al, Ti, Ta, Nb, Hf	Raynor and Silcock, 1970; Balikci et al., 2000; Mignanelli et al., 2014; Hisazawa et al., 2017
Order strengthening	The ordered nature of the γ' phase, coupled with its coherency with the γ matrix, leads to complex faults forming within the γ' phase as a result of plastic deformation. These modify the energetics of the structures further affecting dislocation motion. Anti-phase boundaries, complex stacking faults, and, superlattice intrinsic and extrinsic stacking faults, all may form within the γ' phase. A summary of the deformation mechanisms active in the alloy CMSX-4 at different temperature and creep stresses can be found in the cited paper by Barba et al. The relative energies of the faults can be modified to further increase strength and modify mechanical performance. However, while their importance for the mechanical properties of superalloys is undisputed, experimental determination of these fault energies is complicated and an area of continued research.	Al, Ti, Ta, Nb, Hf	Raynor and Silcock, 1970; Barba et al., 2017
Coherency strengthening	Coherent precipitate interfaces can store a significant amount of energy in the form of misfit stress, and thus may act as energy sinks for dislocations, resulting in the formation of interfacial dislocation networks. Depending on the vector of the stored interfacial edge dislocations and glissile mixed dislocations a repulsive force might provide an additional barrier against precipitate shearing but on the other hand might provide the leading dislocation segment needed to form the superdislocation pair required to shear the precipitate phase.		Gerold and Haberkorn, 1966; Gerold and Pham, 1979; Goodfellow et al., 2019

Directorate-General for Research and Innovation, Flightpath 2050: Europe's vision for aviation: maintaining global leadership and serving society's needs, Publications Office, 2011 – see website list: 2] will result in a systemic transformation to the applications of superalloys, the environments in which they operate, as well as both the development of their chemistry and manufacturing. Considering the demands placed upon jet engines alone, several innovations are currently being evaluated to not only reduce greenhouse gas emissions, but also consider the embodied carbon emissions of engines. The discussion included below, albeit brief and non-exhaustive, provides a glimpse into the complexity of decarbonization, and thus the future of superalloys through the effects of the proposed solutions on superalloy design and manufacture.

Future propulsion systems

The aerospace industry is under tremendous pressure to explore ways through which carbon emissions can be reduced, focusing primarily on net-zero and true-zero propulsion concepts.

The leading net-zero technology currently being explored, particularly in the context of long-haul aviation, is the use of sustainable aviation fuels (SAF) in conventional engines. Critically, SAF usage is often also referred to as a “drop-in” solution, as it does not necessitate a fundamental change in the architecture of engines, enabling immediate reductions in emissions. Briefly, SAFs are made from organic waste products such as plant-based cooking oils and have the potential to reduce carbon emissions by

80% across their lifecycle [see website list: 3]. A number of engines from notable manufacturers are already certified to fly with a mixture of up to 50% of SAFs fuels. However, regulatory pressures further complicate the matter, particularly in terms of mandated mixture ratios, that are sought to be imposed on airlines refuelling, for example, in the European Union in the future. A further key challenge of SAFs is their low production rate, with only 100 million liters of SAFs produced in 2021, attracting severe criticism on the sustainability of SAFs as viable, longer-term solutions [see website list: 3]. From the perspective of the superalloys field, the usage of SAFs is a fairly uncomplicated solution due to their “drop-in” nature, as no dramatic changes are expected to the overall conditions encountered within the jet engine, with perhaps only a consideration to the corrosion behavior of the materials. While unambitious for the development of the superalloys field, the usage of SAFs would allow the exploration of embodied carbon considerations to be developed without the added pressures of changing design properties. Thus, this would build confidence within the supply chains, enabling developments in superalloys compositions and manufacture to be realized faster and be adapted quicker for novel true-zero propulsion systems.

A second, perhaps less widely discussed solution that targets both reductions in carbon dioxide as well as nitrogen oxide, is water rich combustion [see website list: 4]. First developed in a military context with engines like the F-402 to increase thrust at take-off, the concept is also able to reduce fuel consumption and nitrogen oxide emissions for water to fuel ratios below 1 in civil engines like the CFM 56-7B, in particular for short haul flights of up to 1000 km distance according to the study by Zahid (2022). Much like in the case of SAFs, water-rich combustion does not fundamentally alter the jet engine and the associated mechanical properties required of the superalloys within the turbine. However, little research is available that explores the effects of water-rich atmospheres on the properties of superalloys. Thus, while the design criteria are unchanged, the intrinsic performance of superalloys in water rich environments remains a critical limitation to the adoption of water-rich combustion.

In the exploration of other fuel alternatives, the use of hydrogen has dominated the discussion. Unlike SAFs and water-rich combustion, the use of hydrogen fuel is not a “drop-in” solution but would necessitate architectural changes to the turbine [see <https://www.rolls-royce.com/media/press-releases/2022/18-07-2022-rr-announces-leading-edge-hydrogen-programme-and-developments-in-hybrid.aspx>]. Several challenges persist with hydrogen fuels, particularly due to the low fuel energy density, leading to fuel storage considerations. Furthermore, before a hydrogen fuel solution can be considered true-zero, the more fundamental challenge of green hydrogen generation needs to be addressed. Despite these foundational challenges, hydrogen has emerged as the most likely zero-carbon fuel alternative for aviation, posing a considerable development consideration to the field of superalloys. Hydrogen-rich environments are known to lead to embrittlement in several classes of alloys, and γ' -superalloys are no exception, with some alloys being particularly prone to embrittlement at the expected operating temperatures (Dollar and Bernstein, 1988; Chen and Wilcox, 1990; Tarzimoghadam et al., 2017). To date fundamental questions remain, such as how hydrogen interacts with the defects and solutes contained in today's superalloys for cyclic test conditions. Crucially, the inadequate infrastructure for such testing and characterization in hydrogen-rich environments is impacting on the pace at which innovations can be realized in the field. However, new hydrogen research centers currently being planned and built, seek to close this gap within the decade.

While alternative fuel combustion concepts are dominating the discussion for long-haul aviation, technologies such as hydrogen fuel cells and electric propulsion are paving the way for short haul, regional aviation [see <https://www.rolls-royce.com/media/press-releases/2022/19-07-2022-easyjet-and-rr-pioneer-hydrogen-engine-combustion-technology-in-h2zero-partnership.aspx>, <https://www.bayern.de/freistaat-macht-weg-frei-fr-das-wasserstoffzentrum-pfeffenhausen-umsetzungsphase-kann-beginnen/>, <https://www.mtu.de/technologies/clean-air-engine/flying-fuel-cell/>]. These technologies are continuously gaining in interest and pose a range of technological challenges for the materials community, in particular for functional materials. However, the fundamental change in propulsion and the inherent reduction in the operational temperatures of the systems, means indeed that superalloys would no longer be necessary.

Embodied carbon

In addition to net-zero concepts, an area through which the aerospace propulsion industry is seeking to explore immediate impact in terms of emissions, is that of embodied carbon in existing propulsion products, e.g. through systemic changes to manufacturing practices, repair and recyclability technologies and/or usage of raw materials. The realization that the production of engine components today is particularly intensive in terms of emissions and environmental impact has led to several initiatives for the aerospace supply chains, such as the establishment of the International Aerospace Environmental Group (IAEG) [see website list: 9]. Efforts to reduce emissions along the production chain of engine manufacturers are quantifiable according to the emissions Life Cycle Assessment (LCA) outlined in ISO14014, allowing quantitative comparisons of engine parts at critical stages along the production chain [see <https://www.iaeg.com>]. Methods to reduce the negative environmental impact associated with production include: design for longevity, component repair, recyclability, manufacturing powered by green energy sources and reductions in the manufacturing waste.

One method to reduce part specific production waste is by introducing AM components. AM parts have the potential to save significant amounts of production energy, as the ability to produce near net shape components both decreases material waste, while also leading to a reduction in additional post-processing operations, such as machining, that further reduce the embodied carbon of the technology. In addition, AM offers the ability to build complex designs previously inaccessible with conventional subtractive manufacturing. Thus enabling, for example, complex cooling channels to be embedded within parts, leading to significantly enhanced component longevity. However, despite the numerous potential benefits of AM, a particular challenge that has limited its widespread industrial uptake for critical parts is quality assurance and repeatability. For example, it is critical that the mechanical properties of AM components can be correlated with local microstructures, particularly for complex parts where the process

parameters can lead to spatially resolved microstructures, and thus properties. Nevertheless, the improved scientific understanding of microstructural control utilizing AM, coupled with the active integration of control systems, will usher substantial developments over the next decade and support the efforts on the establishment of standards and certification of an increasing number of components manufactured through AM methods.

Aside from the carbon emission reductions that may be realized through careful consideration of the manufacturing practices employed for superalloys and beyond, the stability of the supply of the raw materials needed for superalloys as well as ethical considerations for mining practices are also critical in substantially improving the sustainability of the field. Recycling of superalloys can be seen in light of its positive influence on reducing the environmental impact of mining and the energy intensive refining processes required for the key elements found in superalloys. While currently not widely utilized, recycling, and particularly alloy design with revert considerations in mind, are continuously expanding in interest and the industry is mindful of improving performance. To further understand why recycling practices might become increasingly more relevant in the field, the following section will examine the considerations and factors surrounding the supply of superalloy elements.

Considerations around securing the supply of superalloys

Leaving short term political measures aside, securing the long-term supply of superalloys can be expressed in terms of their element prices, element supply, and reserves. This section examines these three pressure factors briefly in their historical context on the use of the Pt-group metals Re and Ru, that are routinely used in turbine blade materials.

Element cost

Ni-based superalloys consist on average of nine alloying elements beside nickel. Most common are Co, Cr, W, Ta, Al, Mo, Ti, Re and Ru (a Pt-group element). Fig. 6 compares the historic average prices of a number of these key elements (from 1960 to 2019) and includes a red curve that charts the price of Kerosene for a full A380 fuel tank for comparison (note the y-axis is logarithmic). Three key observations can be made from Fig. 6.

Firstly, the price of Re dramatically spiked in the late 2000s and pressured engine manufacturers to develop a new group of alloys that were able to deliver good creep properties with a significantly reduced Re content. Successful alloys developed include the alloy CMSX-8 by Cannon-Muskegon (Wahl, 2012) and the alloy Rene N515 by General Electric (Schafrik, 2016).

Secondly, the prices of Platinum group elements show an upward trend. A number of recently patented nickel-based single crystal superalloys have additions of Ru (a Pt-group element), see alloys for turbine blades section (Koizumi et al., 2004). Despite their enhanced creep properties, see Fig. 4, the alloy prices of these alloys are principally driven by the addition of Ru.

Thirdly, the price of Kerosene for one long-haul flight is equivalent or higher than all element prices (per ton) plotted, with the notable exception of Re and Ru. The addition of about one kilogram of Re to a turbine blade cluster can result in significant net savings in emissions and money. Re-containing blades exhibit significantly higher creep lives (compare Fig. 4 and Table 1), and thus allow the manufacturers to raise the combustion temperature, which in turn results in an efficient fuel burn, thereby providing significant fuel savings [see <https://ec.europa.eu/environment/ipp/lca.htm>].

Element production rates

Generally, elemental costs are a combination of element production rates and industrial demand. Fig. 7 plots the production rates of key Ni-base superalloy element additions from 1960 to 2018. The following observations can be made.

On average, production rates for superalloy elements have increased gradually and seemingly in line with industrial demand, as production rates largely scale with element prices. Despite the energy intensive extraction methods, the average production rates and prices seem to not be impacted by the volatility and mid-term price dynamics in the energy market. Lastly, the production rates of the two elements, Re and Ru, associated with significant creep life improvements for turbine blades (see earlier section) are very low.

Fig. 6 Historical development of key superalloy element prices compared against the Kerosene price of a full A380 fuel tank. The element prices were extracted from the US National Mining Information Centre of the United States Geological Survey [see <https://www.usgs.gov/centers/national-minerals-information-center>].

Fig. 7 Historical production rates of key superalloy elements. The element production rates were extracted from the US National Mining Information Centre of the United States Geological Survey [see <https://www.usgs.gov/centers/national-minerals-information-center>].

The production rate of Re is lower (48.6 t in 2018) than that of all platinum group elements (471 t in 2018). However, when considering only the Pt-group element Ru, an annual global production of 30.5 t was reported in 2018 (cite USGS).

The two alloying elements with highest impact on high temperature creep properties, Re and Ru do not only have low production rates but also originate from very few suppliers worldwide, Fig. 8.

Fig. 8 Regional Re, Ru and Pt production shares as well as Re and Pt Group regional reserve shares. The data was extracted from the US National Mining Information Centre of the United States Geological Survey [see <https://www.usgs.gov/centers/national-minerals-information-center>].

More than half of all Re production and reserves come from Chile (see Fig. 8). For Ru, this dependence is even more pronounced, with 91% of all production and reserves originating from the UG2 orebody of the Bushveld Complex in the Republic of South Africa. Due to the low primary production rates the supply chain is quite consolidated from ore to refined product.

These dependencies point toward the necessity to efficiently recycle high Re and Ru containing superalloys to ensure their long-term availability to the industry.

Conclusion

This chapter has sought to provide a brief overview of superalloys, their development, applications, physical metallurgy, and future considerations. Much like the development of most materials, superalloys have been born out of necessity, and their study, to this day, is closely aligned to industrial need. Although superalloy development has been heavily influenced by the aerospace industry, the exceptional combination of mechanical performance and environmental stability at high temperatures, have seen superalloys become the material of choice for structural applications in high-temperature and/or highly corrosive environments, with increasing utilization within the energy sector.

The future of superalloys is a future tied closely to energy supply and regulation. Legislation centered around decarbonization is expected to spur a new wave of innovation, both in terms of carbon-free production processes as well as alloy compositions that can deliver carbon-free engines for transportation and energy production. Furthermore, the intricate challenges of sustainability and the stability of supply of key elements, are likely to feature prominently in the design and utilization of superalloys in the future. It remains to be seen where the field of superalloys is headed, particularly for aerospace applications, and what future superalloys may have in net-zero engines is yet unknown. Nevertheless, the unique property balance that superalloys exhibit makes them uniquely suited for applications in the most extreme of environments and most damage critical parts across a number of industries.

Abstract

This chapter presents the key properties of copper and copper alloys. This presentation is based on structure-property relationships and comes alongside with insights into production and processing of copper and its alloys. The economically most important copper grades and alloys are presented, and specific measures and problems are highlighted.

[☆]*Change History:* October 2022. The update was made by J. Freudenberger and L. Tikana. The text of any section was updated, while many figures from the initial version are taken to the updated version. Some figures were deleted and also new figures and tables were added (i.e. Figs. 1, 2b, 4, 17, 18, 19, 23b, 24, 28, 32, 36, 43; Tabs. 3, 4, 6, 7, 9). New passages were added to the chapter (Cu-Ag alloys, Cr- and Zr-copper alloys, Cu-Ni-Si alloys, ODS alloys, property relationships, manufacturing processes, additive manufacturing).

Key points

- Copper is soft, malleable, ductile, and has an excellent conductor of heat and electricity, and it resists corrosion.
- The excellent conductivity of copper and most of its alloys is the key factor determining the area of application of the alloys.
- Brass and bronze are the most common copper alloys, though many more are in use.
- In terms of industrial use, copper ranks third, behind iron and aluminum, while copper is a 100% recyclable metal.
- The properties of copper and its alloys are driven by structural features being tuned by processing conditions.

Introduction

Copper is one of the first metals known to mankind. Besides natural materials, copper was the only metal used for more than 10,000 years to particularly make tools. The oldest water pipe made from copper with a length of approx. 400 m was dated back to 2500 BCE. Even before, objects were made from copper, particularly tools, household utensils, jewelry and weapons. After copper had been shaped by simple hammering at the beginning of its discovery, copper was already melted and cast into molds at this time. The trade in copper and objects made from it can be proven at this time by similar finds. All this makes copper the metal of mankind, since it is strongly bound to the intellectual and intercultural development of mankind as well as boosts the modern development of industry and society. Meanwhile the applications of copper and its alloys broadened, nevertheless, its use in the supply of water is still an important application due to its forming and anti-bacterial properties. In modern life copper is mainly used because of its excellent thermal and electrical conductivity in electronic and electrical devices. This chapter provides an introduction to the processing chain of copper from ore to metal alongside with the description of structure-property relationships of the most relevant copper alloys at presence.

Copper production

Copper is one of the few metals that are found in their native state. For this reason, Copper is known to ancient civilizations and is applied for over 10,000 years. This makes it the first and longest used metal, as even today copper is used in almost all areas of modern life. Even though copper occurs in nature, traces of copper can be found virtually in all rocks. In fact, the copper content in the earth's crust is about 0.006%, placing copper in 23rd place of the most frequent elements. Due to its high affinity for sulfur, copper is most often found in sulfidic form. Although the sulfide ores have a significantly lower copper content than the minerals, they are mainly used for copper production as they occur in larger deposits. Most copper ores contain 0.5% Cu or less, iron being the principal metallic impurity. The ores are ground to a fine powder and concentrated (normally by floatation) to 20–25% Cu. This concentrate is melted as a matte of mixed Cu and Fe sulfides containing up to 60% Cu. The matte is oxidized to remove the iron as an oxide and burn off the sulfur. The product is called blister copper which contains 98.5% Cu. Blister copper is fire refined to a tough-pitch (99.5% Cu). It is, then electrolytically refined to 99.99% Cu. Au, Ag, and Pt metals are recovered from slime.

In the period 2010–2020, 207 Mt. of copper have been mined, while reserves have grown to 870 Mt. In 2021 the global copper mine production reached 21 Mt. The largest producer of mined copper is Chile (5.6 Mt). Refinery production in 2021 reached 24 Mt., while China is the largest producer thereof (10 Mt). The total refined copper number encompasses presently, recycled copper from copper contained in end-of-life products contributes to about 1/3 of the total copper supply (ICSG, 2021). Fig. 1 shows the global distribution and major countries of copper production in 2021.

Fig. 1 Most relevant world mine and refinery production of copper, given in kt, in 2021 (USGS, 2022).

Properties of copper

Copper is used mainly because of its high thermal and electrical conductivity. In fact, it shows the second highest values upon all metals at room temperature, just silver has a slightly higher conductivity at a significant higher price. Accordingly, about 2/3 of pure and low alloyed copper is used in electrical industry. Besides this, copper has a high ductility easing forming processes and good corrosion resistance as well as anti-microbial effect. The reddish color is a unique feature of copper. With the exception of gold and copper other metals appear silvery in color.

The physical properties of copper are listed in Table 1.

Uses

Copper and copper-based alloys are used in a variety of applications that are necessary for a reasonable standard of living. Its continuous production and use are essential for society's development. How society exploits and uses its resources, while ensuring that tomorrow's needs are not compromised, is an important factor in ensuring society's sustainable development. Fig. 2a shows the principal uses of copper per properties. Its excellent electrical conductivity accounts for most of its use, principally as wire. Corrosion resistance, thermal conductivity, formability, and unique color account for almost the rest of the consumption of copper. Copper is

Table 1 Physical properties of copper.

Physical property	Value
Atomic number	29
Atomic mass	63.546 amu
Stable isotopes	^{63}Cu 69%, ^{65}Cu 31%
	All other isotopes have very short half-lives (<13 h)
Crystal structure	f.c.c.

used in computers, electrical appliances, gears, bearings turbine blades, cookware, generators, motors, transformers, locks and keys, just some of the none-exhaustive list of end-use products exploiting copper's advantages. Fig. 2b shows the share of copper uses per market sectors.

Electrical properties

In order to ease the comparison of the electrical conductivity, the International Annealed Copper Standard (IACS) was established in 1914 by the US Department of Commerce. The standard was empirically derived upon the electrical conductivity of commercially available copper. This conductivity is used as benchmark value of 100% IACS. As this definition was not made for copper of highest purity, it should not be surprising that these grades come up with an electrical conductivity of 104% according to the IACS standard. This shows that the electrical conductivity strongly depends on the impurities within the material.

These impurities depend on the refinery process. However, it appears not relevant to the applicant which process has been used, but the properties of the copper are. Therefore, copper is graded into oxygen-containing copper, deoxidized copper and oxygen-free copper. If oxygen remains in the copper, it is sensitive to hydrogen sickness. In consequence the metal must be deoxidized, which is commonly performed with the addition of phosphorous. The excess in phosphorous is incorporated into the matrix causing a severe drop in conductivity. The highest conductivity is observed in non-deoxidized oxygen-free copper.

All impurities raise the electrical resistivity of copper. At low concentrations, the increase is proportional to the concentration of the impurity. In general, the effect of solutes in raising the resistivity is greater for large differences between the atomic diameter of the solute and that of copper as shown in Fig. 3. Also solutes of high valency (P, Si, and As) have a greater effect on the resistivity than those of low valency such as Ag, Au, and Cd.

Color

One outstanding characteristic of copper is that the metal shows a distinctive red-orange color. This is since copper has poor reflectivity in the ultraviolet range of the spectrum, whereas the reflectance in the infrared range is very good. In contrast to this, the reflectance of silver is almost constant and very good in the whole range of visible light. The dependence of reflectivity on the

Fig. 3 All impurities increase the resistivity of copper (ASM, 2001).

Fig. 4 The color of copper is a result of the dependence of reflectivity on wavelength. Data from Refractiveindex (2022) *Optical Constants of the Elements*. Available at: <https://refractiveindex.info> (Accessed: 18. April 2022).

wavelength of copper is shown in Fig. 4 in comparison to that of silver (Refractiveindex, 2022). Metals like copper (and gold) have a color because they have an adequate external electronic configuration $s^1d^{10} \leftrightarrow s^2d^9$ and the sublevels s and d are close enough to allow the mentioned transition to occur.

Deformation mechanisms

Copper is deformed predominantly by dislocation glide at room temperature. The slip system in copper, as in all other metals with a face centered cubic symmetry of the unit cell is $\{111\} \langle 110 \rangle$, while the critical shear stress for slip amounts to approx. 3–4 MPa. Failure of copper is ductile. Deformation may also be driven by other mechanisms upon altering surrounding conditions. Mechanical twinning occurs as soon as the critical stress for twinning is achieved, i.e., approx. 140 MPa. As in other materials with face centered cubic symmetry of the unit cell the twin system is $\{111\} \langle 112 \rangle$. This deformation mechanism is activated, e.g., at sufficient strain hardening, small grain sizes in the ultra-fine grained region, or at low temperatures, when dynamic recovery is suppressed. A grain-size in the nanometer region activates grain rotation and grain-boundary sliding as special deformation mechanisms. Ultra-fine grained copper exhibits high strengths and low ductility, and their ductility decreased with decreasing grain sizes, which limited their applications. The limited uniform deformation results from the restricted dislocation activities in the ultra-fine grains and localized deformation. A dominant surface feature of the localized deformation is the appearance of shear bands. Twinned copper shows an intense intrinsic size effect, i.e., thinner twin spacing causes larger strength. When the temperature is lowered below room temperature, the extent of work hardening increases as indicated in Fig. 5 (Blewitt et al., 1955).

Fig. 5 Tensile stress–strain curves for copper crystals at temperatures down to 4.2 K. Adapted from Blewitt TH, Coltman RR, and Redman JK (1955) *Proceedings of the Conference on Defects in Crystalline Solids*, Bristol, p. 369. London: Physical Society.

Fig. 6 The critical shear stress for twinning decreases with decreasing stacking fault energy (○, Cu–Zn; □, Cu–Al; △, Cu–Ge). Adapted from Venables J.A. (1965) In: Hirth, Rogers (eds.) *Deformation Twinning, Proceedings of the Metallurgical Society Conference*, vol. 25, Reed-Hill, R.E., et al. AIME Physical Metallurgy Committee.

While the formation of mechanical twins is favored at low temperatures in copper it is also affected by the crystal orientation as well as the stacking fault energy. There is clear evidence that in metals with a high stacking fault energy, mechanical twinning virtually does not occur, while materials with a low stacking fault energy twin easily under a mechanic load. In copper alloys, twinning depends on the stacking fault energy. The critical resolved-shear stress for twinning is lowered by solid solutions that reduce the stacking fault energy (see Fig. 6) (Venables, 1965). It is significant that copper is not embrittled at low temperatures and does not fracture by cleavage, because of which copper finds use in cryogenic equipment.

Commercial grades of copper

There are several commercial grades of copper. The principal use of oxygen-free copper (C10100) with a minimum of 99.99% Cu is for wire. Also, chemical, or physical vapor deposition techniques, used in microelectronics, rely on highest purity. Fire-refined tough-pitch copper (C12500) is containing between 0.02% and 0.05% oxygen in the form of Cu_2O and ~0.5% other elements. Electrolytic tough-pitch copper (C11000) contains up to 0.04% oxygen. The copper–oxygen phase diagram is shown in Fig. 7 (ASM, 1973). There is a eutectic at 0.38% oxygen and 1066 °C. Fig. 8 is a typical microstructure of cast tough-pitch copper showing primary copper dendrites surrounded by a copper–copper oxide eutectic.

Fig. 9 The copper–lead phase diagram. Data from ASM (1973) *ASM Metals Handbook*, 8th edn., vol. VIII. Materials Park, OH: ASM.

Often tellurium ($\sim 0.5\%$) or sulfur ($\sim 0.5\%$) is added to copper to promote free machining. As oxygen presents in copper can be detrimental when processed at high temperature in hydrogen atmosphere (risk of hydrogen disease), several deoxidized, frequently done with phosphorus, commercial copper classes exist. Deoxidation leaves residual phosphorus in solid solution, which characterizes the class (0.015–0.04% for C12200). This lowers the conductivity to below that of oxygen-free and even tough pitch copper. If the deoxidized copper is to be used for conductivity reason, the residual phosphorus in solid solution is less than 0.01% as is the case for the deoxidized class C10300 with 0.001–0.005%P.

Lead is also added (up to 1%) to copper to form free machining characteristics. However, there are regulatory restrictions for the use of lead as alloying element. Lead is virtually insoluble in copper as shown by the copper–lead phase diagram (see Fig. 9). Lead particles appear as a separate phase in the grain boundaries (see Fig. 10).

Bismuth has a similar effect on the machinability like lead but is a very detrimental impurity. It completely wets the grain boundaries and because it is brittle, its presence renders copper brittle. It must be kept $< 0.003\%$.

Fig. 10 Lead appears as a separate phase in copper alloys. Adapted from ASM (2001) *Copper and Copper Alloys*, ASM Speciality Handbook. ASM: Materials Park, OH.

Copper alloys

Copper is too soft for structural applications. Its strength is markedly increased by alloying. For dilute substitutional solutions (see Fig. 11) (Linde et al., 1950), the yield strength increases in proportion to the solute concentration. The rate of this increase is proportional to the 4/3 power of a misfit parameter defined as $\epsilon = (da/a)/dc$, where da/a is the fractional change in the lattice parameter (a) with concentration c , expressed as an atomic fraction of solutes,

$$\Delta\tau/\Delta c = CG\epsilon^{\frac{4}{3}}$$

where G is the shear modulus of copper and C is a constant. The misfit, ϵ , is the fractional difference of atomic diameters of copper and solute. Fig. 12 shows the misfits for several solutes. On an atomic basis Sb, Sn, and In are the most potent hardeners (Linde and Edwardson, 1954).

The stacking fault energy has a strong influence on the active deformation mode as well as on the capability of grain refinement, thus hardening. It is well promoted, that lowering the stacking fault energy (as well as lowering the temperature) follows the promotion of deformation twinning via dislocation slip. Although different measurements of the stacking fault energy of pure copper have ranges from 40 to 169 mJ m⁻², the best estimate is probably 45 mJ m⁻². Zinc, tin, and aluminum form solid solutions that lower the stacking fault energy to <5 mJ m⁻² at high concentrations as shown in Fig. 13. A lower stacking fault energy leads to more strain hardening. The value of n in the power-law equation,

Fig. 12 The effect of the atomic misfit on the strengthening effect of the solute. Data from Linde J0 and Edwardson S (1954) Investigation of the critical shear stress for single crystals of metallic solid solutions 2. *Arkiv für Fysik* 8, 511.

Fig. 13 The stacking fault energy of alloys (■ Cu–Zn, ▲ Cu–Al, ● Cu–Ge). Adapted from Venables J.A. (1965) In: Hirth, Rogers (eds.) *Deformation Twinning*, *Proceedings of the Metallurgical Society Conference*, vol. 25, Reed-Hill, R.E., et al. AIME Physical Metallurgy Committee.

$$\sigma = K\epsilon^n$$

increases from ~ 0.4 for pure copper to ~ 0.6 or 0.65 at 35% Zn. The greater strain hardening raises the tensile strength as shown in Fig. 14.

One reason for the hardening low stacking fault alloys is seen in the formation of deformation twins yielding a smaller grain size. Finer grain size also increases strength. The grain-size (D) dependence of the yield strength (σ_Y) follows the Hall–Petch relation

$$\sigma_Y = \sigma_0 + \frac{K_{HP}}{\sqrt{D}}$$

Here K_{HP} is the Hall-Petch constant. Besides the given solid-solution and grain size strengthening, copper alloys are also hardened by precipitation hardening, oxide dispersion strengthening and work hardening as discussed below.

Fig. 14 The effect of zinc content on increasing the tensile strength. Finer grain size has a similar effect. Adapted from ASM (2001) *Copper and Copper Alloys*, ASM Speciality Handbook. Materials Park, OH: ASM.

High copper alloys

In some cases, however, the individual properties of pure copper may not be adequate for a particular application. Relatively small amounts of other elements can significantly improve one or more properties of pure copper, such as its strength, softening temperature and machinability, while other properties, such as electrical and thermal conductivity and workability are kept as high and good as possible. Alloying elements include beryllium, chromium, cobalt, iron, magnesium, manganese, nickel, phosphorus, silicon, silver, sulfur, tellurium, tin, titanium, zinc, zirconium, and can be used either individually or in combination. A number of these alloying elements, such as manganese and silicon, cause a relatively strong decrease in conductivity (Fig. 15), but they also improve the material's high-temperature stability, its suitability for welding and its resistance to corrosion. The extent to which the material's properties are modified also depends strongly on the quantity of alloying elements added. In most of these alloys the concentrations of the individual alloying elements remain below 1–2% and the cumulative concentration is under 5%. There are clusters of alloyed copper with their property range (see Fig. 32).

Fig. 15 Influence of alloying elements on the conductivity of copper (DKI, 2018). From Pawlek F., Reichel K. (1956) Der Einfluss von Verunreinigungen auf die elektrische Leitfähigkeit von Kupfer. *Zeitschrift für Metallkunde* 47: 347–351.

The response of these materials to changes in temperature is striking, as no embrittlement is observed even down to temperatures as low as -200°C .

This class of materials, called in UNS "*high copper alloys*" do not fall into any other copper alloy group. It is essentially composed of a number of non-age-hardenable and age-hardenable alloys. Non-precipitation-hardenable alloys are those whose strength can only be improved by cold working. The strength of precipitation-hardenable alloys on the other hand can be improved by cold working and, in particular, by suitable precipitation heat treatment.

The age-hardening behavior is based on the fact that the solubility of the mentioned alloying elements in Cu decreases with decreasing temperature. On this basis, a heat treatment is applied that leads to age hardening. A high-temperature solution treatment is followed by a low-temperature aging treatment. This serves to precipitate a dispersion of small metastable or stable particles, which give rise to hardening by several hardening mechanisms that depend in detail on the microstructural, chemical, crystallographic and mechanical properties of the precipitated particles.

Copper silver alloys

Commercially available copper-silver alloys contain less than 1% Ag, between 0.03% and 0.12% Ag and exhibit a single-phase microstructure. Though they are not aged-hardenable. These silver concentrations already cause an increase of the softening temperatures vis-à-vis pure copper. Different classes of copper-silver alloys exist, subdivided in oxygen-containing, oxygen-free and phosphorous deoxidized containing varying concentrations of silver.

The copper-rich f.c.c phase has a maximum solubility of approx. 8% silver at the eutectic temperature of 779°C , while the solubility vanishes at room temperature. Hence, copper-silver alloys with concentrations above approx. 2% are age-hardenable. With well-tuned precipitates, copper alloys with 7% silver and traces of Zr exhibit an ultimate tensile strength of up to 1.4 GPa while having an excellent conductivity approx. 80% IACS.

One of the benefits of copper-silver alloys compared to pure copper is that the hardness achieved through cold working the material can be maintained even at relatively high temperatures. The softening temperature of CuAg0.10 is around 300°C . A further outstanding property of these materials is their relatively high creep rupture strength, which is of major significance in applications subjected to mechanical stress at elevated temperatures.

The main applications of copper-silver alloys are inter alia high-strength catenary wires (for high-speed trains); commutator segments and rotor windings in electric motors; transformers and generators that are subjected to high-temperature stresses.

Beryllium copper

Copper alloys containing 1.8–2.0% Be and 0.2–0.8% Ni + Co are precipitation-hardenable. The alloy C172000 is solution treated at $\sim 800^{\circ}\text{C}$ and rapidly cooled. The precipitation is done between 300°C and 400°C . Fig. 16 shows the copper-rich end of the Cu-Be phase diagram. Precipitation hardening produces very high strengths. Even higher strengths can be achieved by cold working after the solution treatment and before precipitation as shown in Table 2. The principal drawback is that the toxicity of beryllium is an extreme danger in preparing this alloy.

Fig. 16 The copper–beryllium phase diagram. Adapted from ASM (1973) *ASM Metals Handbook*, 8th edn., vol. VIII. Materials Park, OH: ASM.

Table 2 Strength of beryllium copper sheet (C17200).

Condition	Yield strength (MPa)	Tensile strength (MPa)
Annealed	250	465
1/4H	485	570
1/2H	555	605
H	690	730
Annealed & HT	1060	1260
1/4H & HT	1125	1290
1/2H & HT	1180	1325
H & HT	1195	1360

HT indicates age-hardening treatment. Solution treatments were done prior to work hardening.

Data from ASM (2001) *Copper and Copper Alloys*, ASM Speciality Handbook. ASM: Materials Park, OH.

Chromium and zirconium copper

Chromium copper (C18050) contains up to 1% Cr. The maximum solubility of chromium in copper is only 0.65% at the eutectic temperature of 1075 °C and this very low value decreases significantly with decreasing temperature. At 400 °C, the solubility of chromium in copper falls to below 0.03%. As a result of this temperature solubility dependence, the chromium can be precipitated and these alloys can therefore be age-hardened. Fully heat-treated chromium copper can reach a conductivity of 85% IACS.

Zirconium copper (C15000) contains 0.13–0.20% Zr. It can also be heat treated to yield strengths of 400 MPa while retaining a conductivity of 84% IACS.

The advantages of CuZr are its high softening temperature and creep rupture strength and its notch strength insensitivity at elevated temperatures. A disadvantage of copper-zirconium alloys is that they exhibit only minimal precipitation hardening. CuCr, in contrast, exhibits good strength parameters in its precipitation-hardened state. However, the relatively high notch sensitivity of CuCr at higher temperatures can be a disadvantage in certain situations. The beneficial properties of each of CuCr and CuZr can be usefully combined in the ternary copper-chromium-zirconium (CuCrZr) alloy system. The characteristics of CuCrZr are:

- high strength at room temperature
- high softening temperature
- improved creep rupture strength

even at elevated temperatures (Fig. 17).

Copper nickel silicon alloys (nickel-silicon bronze)

The high solubility of silicon in copper can be significantly reduced by the addition of nickel and the solubility decreases further with falling temperature. The temperature-dependent solubility of the intermetallic compounds Ni₂Si, Ni₅Si₂ (or Ni₃₁Si₁₂) means that copper-nickel-silicon alloys can be age-hardened. The crystal structures of the silicides are semi-coherent or incoherent with the matrix.

Fig. 17 Resistance to tempering of Cu compared to CuCr, CuZr and CuCrZr, all samples were cold worked before tempering (DKI, 2018).

Commercial alloys

Copper and its alloys are classified as being either wrought alloys or casting alloys, depending on their usage. The unified numbering system (UNS) designations for copper material groups are listed in Table 3.

Sheets produced by cold rolling and rods or wire produced by drawing are sold with a temper designation indicating their state as defined in ASTM B 601. A synopsis of the system is outlined in Table 4.

Brass

Brasses are alloys of copper and zinc. Fig. 20 is the copper–zinc phase diagram. The solubility of zinc in the f.c.c. lattice of copper is >35%. At nearly equal atomic percentages of copper and zinc, there is a b.c.c. intermetallic phase β , that has a wide range of solubility. At temperatures $< \sim 460^\circ\text{C}$, β -brass undergoes an ordering reaction to form an ordered b.c.c. phase β' with a B2 (CsCl) structure. Each copper atom is surrounded by eight zinc and eight copper atoms. A eutectoid transformation, $\beta' \rightarrow \alpha + \gamma$ at 250°C has been reported. However, the transformation is rarely, if ever, encountered.

Zinc provides solid solution hardening to copper. Both the yield strength and the tensile strength increase with zinc content, as indicated in Figs. 21 and 22.

As the lower stacking fault energy increases the exponent n , (as explained in the section “Copper alloys”) the uniform elongation also increases in the power-law approximation of the stress–strain curve. Another effect of the lower stacking fault energy is that

Table 3 Commercial copper alloy families (UNS Standard Designation for Wrought and Cast Copper (copper.org) and Unified Numbering System (UNS) for Copper and Copper Alloys (uncopperalloys.org)).

Group	Description	Designation
Coppers	Metals which have a designated minimum copper content of 99.3% or higher	Wrought
High copper alloys	For the wrought products, these are alloys with designated copper contents less than 99.3% but more than 96% which do not fall into any other copper alloy group. The <i>cast high copper alloys</i> have designated copper contents in excess of 94%, to which silver may be added for special properties	- o Coppers (C10100–C15999) - o High Copper Alloys (C16000–C19999) - o Brasses (C20000–C49999) - o Bronzes (C50000–C69999)
Brasses	These alloys contain zinc as the principal alloying element with or without other designated alloying elements such as iron, aluminum, nickel and silicon. The <i>wrought alloys</i> comprise three main families of brasses: copper–zinc alloys; copper–zinc–lead alloys (lead brasses); and copper–zinc–tin alloys (tin brasses). The <i>cast alloys</i> comprise four main families of brasses: copper–tin–zinc alloys (red, semi-red and yellow brasses); “manganese bronze” alloys (high strength yellow brasses); leaded “manganese bronze” alloys (leaded high strength yellow brasses); copper–zinc–silicon alloys (silicon brasses and bronzes); and cast copper–bismuth and copper–bismuth–selenium alloys. Ingot for remelting for the manufacture of castings may vary slightly from the ranges shown	- o Copper Nickels (C70000–C73499) - o Nickel Silvers (C73500–C79999)
Bronzes	Broadly speaking, bronzes are copper alloys in which the major alloying element is not zinc or nickel. Originally “bronze” described alloys with tin as the only or principal alloying element. Today, the term is generally used not by itself but with a modifying adjective. For <i>wrought alloys</i> , there are four main families of bronzes: copper–tin–phosphorus alloys (phosphor bronzes); copper–tin–lead–phosphorus alloys (leaded phosphor bronzes); copper–aluminum alloys (aluminum bronzes); and copper–silicon alloys (silicon bronzes) The <i>cast alloys</i> have four main families of bronzes: copper–tin alloys (tin bronzes); copper–tin–lead alloys (leaded and high leaded tin bronzes); copper–tin–nickel alloys (nickel–tin bronzes); and copper–aluminum alloys (aluminum bronzes) The family of alloys known as “manganese bronzes,” in which zinc is the major alloying element, is included in the brasses, above	Cast - o Coppers (C80000–C81399) - o High Copper Alloys (C81400–C83299) - o Brasses (C83300–C89999) - o Bronzes (C90000–C95999) - o Copper Nickels (C96000–C96999) - o Leaded Coppers (C98000–C98999) - o Nickel Silvers (C97000–C97999) - o Special Alloys (C99000–C99999)
Copper-nickels	These are alloys with nickel as the principal alloying element, with or without other designated alloying elements	
Copper-nickel-zinc alloys	Known commonly as “nickel silvers,” these are alloys which contain zinc and nickel as the principal and secondary alloying elements, with or without other designated elements	
Leaded coppers	These comprise a series of <i>cast alloys</i> of copper with 20% or more lead, sometimes with a small amount of silver, but without tin or zinc	
Special alloys	Alloys whose chemical compositions do not fall into any of the above categories are combined in “special alloys”	

Table 4 Examples of temper designations for copper alloys (Fundamentals: Types of Copper and Properties).

Temper designation	Temper name or condition
Annealed	
O10	Cast and annealed
O20	Hot forged and annealed
O60	Soft annealed
O61	Annealed
O81	Annealed to Temper ¼ Hard
O5015	Average grain size: 15 μm
Cold worked tempers	
H01	¼ Hard
H02	½ Hard
H04	Hard
H08	Spring
Cold worked and stress relieved tempers	
HR01	H01 and stress relieved
HR04	H04 and stress relieved
Precipitation hardening	
TB00	Solution heat treated
TF00	TB00 and age hardened
TH92	TB00 and cold worked and aged
Manufactured tempers	
M01	As sand cast
M04	As pressure die cast
M06	As investment cast

**Fig. 20** The copper–zinc phase diagram. Adapted from ASM (2001) *Copper and Copper Alloys*, ASM Speciality Handbook. ASM: Materials Park, OH.

annealing twins are much more frequent. Fig. 23 compares the annealed microstructure of copper with brass containing 30% Zn (Hosford, 1993). The microstructures of brass containing 40% zinc or more consist of two phases, α and β . The two-phase microstructure of Muntz metal (40% Zn) is shown in Fig. 24. At 800 °C the microstructure is entirely β , but as the alloy is cooled, α precipitates. The effects of other alloying elements to brass on the solid solubility of zinc can be approximated by “zinc equivalents.” A concentration of 1% tin is equivalent to 2% zinc, so tin has a zinc equivalent of 2. Table 5 lists the zinc equivalents of the common alloying elements. The relative values of the zinc equivalents of the elements can be understood in terms of the number of valence electrons per atom. Silicon and aluminum have high valencies (4 for silicon and 3 for aluminum) and low atomic masses (28 for silicon and 27 for aluminum), so 1 wt% causes a large increase of the electron-to-atom ratio. Magnesium, like

Fig. 21 The yield strength of brasses increases with the amount of cold work and the zinc content. The true strain, $\epsilon = \ln(t_0/t)$ where t is the thickness and t_0 is the thickness before cold rolling. Adapted from ASM (1979) *ASM Metals Handbook*, 9th edn. vol. II. Metals Park, OH: ASM.

Fig. 22 The tensile strength of brasses increases with the amount of cold work and the zinc content. The true strain, $\epsilon = \ln(t_0/t)$ where t is the thickness and t_0 is the thickness before cold rolling. Data from ASM (1979) *ASM Metals Handbook*, 9th edn. vol. II. Metals Park, OH: ASM.

(1993) *The Mechanics of Crystals and Textured Polycrystals*. London: Oxford Science Pub. (Courtesy A Graf).

Fig. 24 Photomicrograph of a brass (42% Zn). The dark phase is β and the light phase is α , which has precipitated during cooling. Source Kupferinstitut.

Table 5 Zinc equivalents of several alloying elements in brass.

Element	Zn equivalent	Element	Zn equivalent
Si	10	Al	6
Mg	-2	Sn	2
Fe	0.9	Mn	0.5
Co	-0.8	Ni	-1.3

zinc has a valency of 2, but the atomic mass of magnesium is less than half that of zinc (24 for magnesium vs 65 for zinc), so 1 wt% Mg has over twice the effect of 1 wt% Zn. Tin has a valence of 4, but its atomic mass (119) is roughly twice that of zinc.

Free cutting brass has been alloyed with lead up to 3% (C36000) to enhance the machinability. Legislative restrictions of certain chemical elements assumed detrimental to human and environment, e.g., Cd, Pb, has led to the development of alternative lead free-cutting brass types in enhancing the zinc content (C28500) or replacing lead by silicon (C69300) or other elements. As lead confers multiple properties to copper alloys (good machinability, lubrication for dry-running, etc.) it is unlikely to find a one to one lead replacement. Not all properties of leaded alloys can be given by the lead free alternatives. Hence the free cutting properties of high silicon brass is given by the presence of a silicon rich phase acting as chip breaker.

Bronze

True bronzes are copper–tin alloys. Tin is much less soluble in copper than zinc as shown in the copper–tin phase diagram (see Fig. 25). The ϵ -phase is very sluggish to form and is rarely encountered. Tin is a potent solid solution strengthener. However, alloys

Fig. 25 The copper–tin phase diagram. β is a b.c.c. phase. In alloys containing $\sim 20\%$ Sn, formation of the ϵ -phase is so sluggish that it is seldom encountered. Adapted from ASM (1973) *ASM Metals Handbook*, 8th edn., vol. VIII. Materials Park, OH: ASM.

with >8% Sn are too brittle to be formed mechanically. Because bronzes have a much greater difference of the liquidus and solidus temperatures than brass, they are much easier to cast. Casting alloys often contain up to 12% Sn, these are extensively for pipe fittings, pumps bodies and up to ~20% Sn for bells.

Wrought alloys contain up to 8–10% Sn. They are mainly used for connectors.

Aluminum bronze

Alloys of copper with aluminum called aluminum-bronze, even though they contain no tin. Aluminum-bronzes containing up to 7% Al behave much like brass. Above 7% a b.c.c β -phase occurs. The phase diagram (see Fig. 26) shows that a b.c.c β -phase transformation into $(\alpha + \gamma_2)$ eutectoid occurs at ~12% Al.

This eutectoid transformation of $\beta \rightarrow \alpha + \gamma_2$ occurs at 565 °C and 11.8% Al. Fig. 27 shows the pearlite-like microstructure of alternating platelets of α and γ_2 in an alloy of Cu–11.8% Al after slowly cooling from 800 °C. With rapid cooling, the eutectoid transformation is suppressed and the alloy transforms by martensitic shear to a new hexagonal phase β' . Fig. 28 shows the martensitic β' needles in the same alloy after rapid cooling. The martensitic reaction is almost instantaneous. It starts when β is quenched below the M_s temperature and is virtually complete when the temperature is at the M_f . The M_s and M_f temperatures depend on the composition as shown in Fig. 29 (Flinn, 1961). The oxidation resistance of aluminum bronzes is somewhat superior to brass.

To enhance the strength and corrosion resistance of aluminum bronze it is alloyed with nickel and iron with a small amount of manganese. This extends the α -phase area and shifts the formation of the corrosion sensitive γ_2 -phase to higher aluminum content (C63000, C95820). These alloys are used for ship propellers, pump bodies and other high-performance parts in the gas and oil industry.

Copper nickel alloys

Copper and nickel are completely miscible in both the liquid and solid state as shown in the copper–nickel phase diagram (see Fig. 30). The low-temperature miscibility gap is rarely encountered.

Nickel imparts improved corrosion and oxidation resistance to copper. Cupronickels containing 10–30% Ni are widely used for tubes in offshore and marine area, heat exchangers and as plates to protect offshore pillars.

Alloying copper with 20% Ni causes a loss of the copper's familiar yellow–reddish color. Coinage accounts for ~1% of the consumption of copper. The five-cent pieces (“nickels”) in the US and Canada are alloys of 75% copper and 25% nickel. The 10-cent (“dime”) and 25-cent (“quarter”) pieces are sandwiches of pure copper core clad with 75% copper–25% nickel alloy as shown in Fig. 31. The Susan B Anthony US dollar is a sandwich of pure copper clad with 77Cu–12 Zn–7 Mn–4 Ni. European coins are either copper-based alloys or combinations of two copper-based alloys. Constantan (45% Ni) has a nearly zero-temperature coefficient of resistivity, hence is useful in instruments.

Shape memory alloys

Cu-based shape memory alloys and among these copper–zinc (Cu–Zn), copper–aluminum (Cu–Al), and copper–tin (Cu–Sn) alloys have shown potential due to their good shape recovery. The martensitic transformation temperature is approx. 100 °C for the Cu–Al–Mn alloys. The exact temperatures depend on composition. The temperature hysteresis is in the range of 15–25 °C. They are considered as cost effective because they are easily produced using conventional processing routes. Further, they show a high electrical and thermal conductivity. However, their applications are still limited due to their low mechanical strength, brittleness and thermal stability. Unfortunately, the binary alloys suffer from bad cold workability and martensite stabilization; hence ternary and quaternary additions are used to improve the properties, which has successfully been done for Cu–Zn and Cu–Al alloys, only. The Cu–Zn–Al alloys with 10–30% Zn and 5–10% Al and the additions of other elements yield to improved mechanical properties, in particular plasticity, while the Cu–Al–Ni alloys with 11–15% Al and 3–4% Ni and the additions of other elements aim at higher transformation temperatures (approx. 230 °C). The Cu–Al–Ni alloys are the only available copper-based high-temperature shape memory alloys. They are, however, very brittle. The recoverable strain for both groups is approx. 4–6%. In addition to the shape memory, superelastic, and pseudoelastic effects, these alloys also present a temperature memory effect, a small hysteresis, and a high damping coefficient.

Property relationships

For all copper alloys, the Wiedemann–Franz law applies. This means that the ratio of the electronic contribution of the thermal conductivity (κ) to the electrical conductivity (σ) is proportional to the temperature. In principle all metallurgical effects that lower the conductivity, i.e., rise the resistance cause an increase in strength. Therefore, there is a balance between conductivity and strength in copper alloys as shown in Fig. 32.

Among the copper alloys, the precipitation hardenable alloys show slightly enhanced combination of strength and conductivity, i.e., they are closer to the upper right corner of this Asby diagram, than solid solutions. This is because the electrical resistance of these alloys is determined upon a parallel arrangement of the individual contributions, giving lower values than the serial arrangement characterizing the solid solution case. In both cases, the strength values are superimposed upon:

$$\tau = \tau_0 + \sqrt[k]{\sum_i \Delta\tau_i^k}$$

Where $\Delta\tau_i$ are the individual contributions to the strength, and k is an exponent ranging from 0.5 to 1 depending on whether the strengthening effects are of similar or dissimilar measure. Table 6 summarizes the composition and properties of characteristic copper alloys as presented before in representative selection.

Fig. 32 Strength of selected copper alloys in relation to their conductivity. The most important groups of copper alloys are labeled.

Table 6 Composition and properties of characteristic copper alloys (Freudenberger and Warlimont, 2018).

Material	UNS No.	Purity; other elements (wt%)	Yield strength (MPa)	Ultimate tensile strength (MPa)	Elongation to failure (%)	Thermal conductivity ($Wm^{-1} K^{-1}$)	Electrical conductivity (Sm^{-1})

Manufacturing processes

Manufacturing is the process of converting raw materials into products, including all intermediate processes involved in the production and integration of a product components. The traditional production of semi-finished products can be structured into melting and casting, hot and cold work with heat treatments and finishing. Additive manufacturing processes overcome this queue. In the following the most important processes to produce copper-based semi-finished products are introduced.

Casting

A large variety of casting processes can be applied of producing copper base alloy castings, which are also commonly in use for iron and non-ferrous metals, as e.g., in particular (i) sand casting, (ii) mold casting, (iii) die casting, (iv) chill casting, (v) centrifugal casting and (vi) continuous casting. Due to the melting temperature and good conductivity, the metal is molten by an induction furnace rather than a combination of gas and electric oven. Permanent metal molds are used on a large scale as they provide enhanced dimensional accuracy and surface finish of the castings. In addition, the higher cooling rate causes grain refinement, and thus an improvement in the mechanical properties. Mainly used are the gravity die casting process and the centrifugal and continuous casting processes for near-net shape castings. The separation between the liquidus- and solidus line ranges from below 50 °C for, e.g., aluminum- and nickel bronzes via an intermediate freezing range of 50–100 °C for, e.g., silicon bronze and -brass to up to 170 °C for, e.g., tin bronzes. In general, alloys with a greater separation of liquidus and solidus are regarded as easier to cast. In a fixed thermal gradient, the length of dendrite L , arms is proportional to this temperature difference, ΔT . Also, the liquid-to-solid shrinkage is a measure to characterize the casting process. A higher shrinkage is seen, e.g., for aluminum- and silicon bronzes. They are more fluid, more easily poured and result in high-grade castings. However, careful design is necessary to promote directional solidification and avoid internal shrinkage and crack formation. The shrinkage during solidification can occur inter-dendritically, what simplifies risering. Lower liquidus temperatures are also beneficial.

Forming

Due to its enormous plasticity and formability, copper is capable of being formed into all types of semi-finished products such as sheet, strip, tube, rod, wire, and die and open die forgings. Cold working at room temperature is easily applied for copper in the recrystallized condition. As cast microstructures do not fulfill this requirement and are partly not easy to deform, hot working at 800 °C to 900 °C, depending on the technique, is applied to obtain a recrystallized microstructure in-situ. Forming processes, such as extrusion, forging, swaging, drawing, rolling and profile rolling, are used to produce semi-finished products without the necessity of cutting in near-final dimensions.

Fig. 33 Forming limit diagrams for copper and copper alloy sheets.

Sheet formability benefits from high strain-hardening exponents and high R -values. The R -value, which is also called the Lankford coefficient or the plastic strain ratio, is the ratio of the true width strain to the true thickness strain at a particular value of length strain, i.e.,

$$R = \varepsilon_W / \varepsilon_t$$

Forming limit diagrams (see Fig. 33) show the combinations of strains that lead to the formation of localized necks. Minima occur near plane strain, $\varepsilon_2 = 0$ (corresponding to ε_2 in Fig. 33). The level of ε_1 at this point depends strongly on the strain-hardening exponent, n in $\sigma = K\varepsilon^n$. Cold-worked sheets tend to have lower forming limits. The forming limits tend to rise with sheet thickness. A high strain-rate exponent m , in

$$\sigma = C\varepsilon^m$$

is also useful in forming. However, it is found to be very low (0.002–0.005) for copper and brass at room temperature.

In deep drawing applied, e.g., for flat bottom cups, the limiting drawing ratio (LDR) which is the ratio between the maximum blank diameter and the punch diameter, depends mainly on the R -value of the sheet material. A large R -value represents resistance to thinning. Because the R -values of copper and brass sheets tend to be <1 , the values of LDR tend to fall between 2.1 and 2.2. Formability in sheet forming that involve biaxial stretching depends mainly on the strain-hardening exponent n . Because of this, copper and especially brass have very good stretchability.

Extrusion and forging

Forging and extrusion are two reliable processes to manufacture copper parts and components, showing very similar results. Forging uses radial compressive forces to shape the material by a custom-made steel die, which can be open or closed. Forged copper parts are exceptionally strong, highly reliable and have tremendous structural integrity. The forging process is less labor-intensive and leaves less scraps behind than extrusion. In contrast, extrusion uses a high pressure to push the copper billet through a die, which can have differently-shaped cross-sections depending on the aimed cross section of the semi-finished product. Hot extrusion reduce

pores and voids, breaks up the cast structure, and creates a more homogeneous microstructure, while cold extrusion gives the final shape a better finish on the surface and adds strength via work hardening. In addition, grains are elongated further increasing the strength. Extrusion is also beneficial with respect to creating long, tubular metal parts that require strict tolerance requirements. Forging of massive parts might show difficulties in meeting these requirements and, thus, cause secondary processing to successfully create the finished shape. Hot forging temperatures for most copper alloys lie in the range of 600–750 °C, while hot extrusion of copper takes place at up to 900 °C, i.e., above 80% of the melting temperature, which is commonly used.

Powder processing

Parts of copper and copper alloys are sometimes fabricated by conventional powder metallurgy that involves pressing powder to the desired shape and sintering to achieve nearly full density. Copper powder can be obtained from various techniques, such as atomization, electrolysis, hydrometallurgy and solid-state reduction. Each of them generates powder having certain inherent characteristics. While atomization generates powder particles having either spherical or irregular shape, electrolysis follows dendritic particles and solid-state reaction tends to porous particles of irregular shape. These powders are then further processed, either by additive manufacturing or sintering. For the later, powders are pressed into nearly the desired shapes at room temperature and sintered at high temperatures below the melting temperature at which the part is fully densified. For sintered parts made from alloys, suitable pre-alloyed powders are used. Alloying constituents with melting temperatures below the sintering temperature, such as lead, favor the sintering process. Besides conventional alloys, sintering techniques are applied to dispersion strengthened copper alloys. After sintering, the parts require calibration. Most sintered parts from copper alloys were used as oil-impregnated, self-lubricating bearings. These parts have a pore space of up to 30%, which is achieved by stopping the sintering before complete densification. These pores act as container for the lubricant.

Additive manufacturing

Traditional forming techniques have difficulties in realizing complex shapes, which can be overcome utilizing additive manufacturing. Selective laser melting (SLM) and selective electron beam melting (SEBM) are the main techniques used for additive manufacturing, besides binder jetting, laser metal deposition and ultrasonic additive manufacturing. Additive manufacturing has shown a strong development in recent years and is expected to become the dominant processing method for parts of complex geometry as well as individually shaped components, always in combination with computer aided design. Liquid copper has an extremely high reflectivity of approx. 98% for laser light with commonly applied wavelengths in the range of 1000–1100 nm. The absorption of the impacted energy can be raised to 25–40%, when wavelengths of 515 nm are utilized. In contrast, the SEBM technology is suitable for the processing of copper as the nature of reflexion differs for electrons and photons. Both, mechanical and physical properties of parts and components are directly influenced by the density of the metal, while a high density is beneficial. The major drawback of SLM against SEBM is related to this issue, since besides the used wavelength, an increasing laser power also causes a higher density of the build parts. When the applied energy density is in the region of 250–750 J/mm³, parts with relatively high density can be obtained. With SEBM being applied, parts with a relative density of >99% can be built easily. Pure copper parts with a relative density of 99.95% build through SEBM have an electrical conductivity of 99% IACS and a thermal conductivity of 400 W/mK.

Deformation textures

During conventional drawing of copper mixed $\langle 1\ 1\ 1 \rangle / \langle 1\ 0\ 0 \rangle$ fiber textures develop with a strong $\langle 1\ 1\ 1 \rangle$ fiber component develops, which is common for materials with a face centered cubic symmetry of the unit cell. The ratio of $\langle 1\ 0\ 0 \rangle$ to $\langle 1\ 1\ 1 \rangle$ increases with alloying. The compression texture of copper has $\langle 1\ 1\ 0 \rangle$ directions parallel to the axis of compression. The development of deformation textures in copper during rolling is different. Most orientations assemble along two incomplete fibers. The rolling texture of copper is described by two continuous fibers: (i) the α -fiber, which runs from the Goss orientation, $\{1\ 1\ 0\} \langle 0\ 0\ 1 \rangle$, to the brass orientation, $\{1\ 1\ 0\} \langle 1\ 1\ 2 \rangle$, and (ii) the β -fiber, which runs from the copper orientation, $\{1\ 1\ 2\} \langle 1\ 1\ 1 \rangle$, over S orientation, $\{1\ 2\ 3\} \langle 6\ 3\ 4 \rangle$, to the brass orientation, $\{1\ 1\ 0\} \langle 1\ 1\ 2 \rangle$.

The corresponding texture is represented schematically in Fig. 34 (Humphreys and Hatherly, 1995).

The rolling texture of low stacking fault energy alloys is different. Here, the brass orientation is much stronger and the fiber between the Goss and Brass orientations is more prominent. There are two additional fibers. Fiber γ corresponds to orientations having $\{111\}$ aligned parallel to the rolling plane. It extends from $\{1\ 1\ 1\} \langle 1\ 1\ 2 \rangle$. Fiber τ consists of orientations with $\langle 1\ 1\ 0 \rangle$ parallel to the transverse direction. Fig. 35 is a schematic representation of the fibers. As the amount of deformation increases the α -fiber remains strong, the β -fiber increases, and the copper and S components decrease.

The relative amounts of these components change as the temperature of rolling decreases or as the copper is alloyed with zinc or another element that lowers its stacking fault energy. The transition from copper-type [recrystallization texture](#) to the Brass-type texture depends on the stacking fault energy of the alloy.

The rolling texture also depends on the rolling temperature.

Fig. 36 Variation of mechanical properties during cold work of OF copper, left. Annealing of a sample that was deformed to an area reduction of 50% causes an energy release depending on the annealing temperature, right. The transition from recovery to recrystallization is most apparent from the change in grain size D , i.e., changes $<250^\circ\text{C}$ are caused by annealing out of vacancies, changes $>250^\circ\text{C}$ are a result of recrystallization and grain growth. Adapted from Wielandwerke (1999) *Wieland-Kupferwerkstoffe, Herstellung, Eigenschaften und Verarbeitung*. Wieland-Werke AG.

the mechanical properties of copper (Wielandwerke, 1999). During cold work, hardness HB , yield strength σ_y and ultimate tensile strength σ_{UTS} increase, while the strain to failure ϵ_f decreases. During recovery, the dislocations glide and re-arrange in energetically favored sites. During this process, the strength slightly decreases and the elongation slightly increases.

Recrystallization

During recrystallization after cold work, new strain-free grains are formed. The extent of recrystallization depends on both temperature and time. It is customary to define the recrystallization temperature as the temperature at which 63% of the grains will be recrystallized in 1 h. This originates from the Johnson Mehl Avrami Kolmogorov equation, in which the fraction f of the microstructure recrystallized at any temperature should be given by

$$f = 1 - \exp \left[- \left(\frac{t}{t_R} \right)^{n_T} \right]$$

Where t_R is the recrystallization time. At $t = t_R$: $f = 1 - (1/e) = 0.63$. For most metals of commercial purity, the recrystallization temperature is between 1/3 and 1/2 of the melting point on an absolute scale. However, the recrystallization temperature depends on purity, the extent of cold work before annealing, and the prior grain size. Fig. 37 shows the kinetics of recrystallization of copper that is 99.999% pure after cold reduction of 98% (Guy and Hren, 1974).

The fact that the recrystallization temperature of 113°C in this case is only 28% of the melting temperature is explained by the extreme purity and very heavy reduction. The time, t , to achieve 63% recrystallization is given by the Arrhenius equation,

Fig. 37 Isothermal recrystallization of 99.999% pure copper cold-worked 98%. Adapted from Guy AA and Hren JJ (1974) *Elements of Physical Metallurgy*, 3rd edn. Reading, MA: Addison-Wesley Publishing Co.

$$t = t_0 \exp \left[\frac{Q}{RT} \right]$$

where Q is the activation energy, R is the gas constant, and T is the absolute temperature. Fig. 38 is an Arrhenius plot of the data in Fig. 37. The activation energy is 92.6 kJ mol^{-1} .

According to the Johnson–Mehl–Avrami–Kolmogorov equation, the exponent n is the sum of the contributions from nucleation n_n and growth n_g . If the nucleation rate is constant, $n_n = 1$ and if the growth rate is constant $n_g = 3$. Fig. 39 is a log–log plot of $\ln(1 - f)$ vs t of the data for Fig. 37 at 135°C . The slope is close to 4, indicating constant nucleation and growth rates.

The effect of the amount of cold work that is applied prior to the recrystallization heat treatment on the evolution of the hardness with annealing temperature is illustrated in Fig. 40 for copper. It is obvious that with increasing cold work a decreasing recrystallization temperature is observed. This dependency is depicted in Fig. 41.

As already mentioned, the recrystallization temperature also depends on the size the grains have prior to annealing. The effect thereof is shown in Fig. 42 for copper being annealed at 225°C . With increasing deformation strain, the recrystallization temperature seen at a subsequent heat treatment lowers or at a given temperature, recrystallization is faster in fine-grained material.

The grain size resulting from recrystallization depends on the relative rates of nucleation and growth of recrystallized grains. Increasing amounts of cold work before recrystallization decreases the resulting grain size because it increases the nucleation rate more than the growth rate. Solutes in solid solution decrease the recrystallized grain size because they decrease the growth rate by slowing grain-boundary motion. Second-phase particles have the same effect but they may increase the nucleation rate. Finally, the grain size before recrystallization affects the recrystallized grain size. With a finer prior grain size, there are more sites for nucleation, so the resulting grain size is also smaller.

Fig. 38 An Arrhenius plot of the time–temperature relation for 63% recrystallization of the copper in Fig. 37.

Fig. 39 A Johnson–Mehl–Avrami–Kolmogorov plot of the recrystallization of the copper in Fig. 34 at 135°C . The slope is nearly 4, which indicates that the nucleation rate is constant and there is a constant rate of growth in three dimensions.

Fig. 43 Time dependence of recrystallization in 99.99% and 99.9% copper during isothermal annealing. Solid curves give their recrystallization fractions as a function of annealing time are fitted by using the classical JMAK model. Adapted from Yao (2021), <https://doi.org/10.1016/j.msea.2021.141786>.

The recrystallization kinetics are heavily influenced by the purity of the material. This causes the recrystallization time, observed at $T = 200\text{ }^{\circ}\text{C}$, to drop from approx. 1 h 22 min to approx. 6 min when the purity rises from 99.9% to 99.99%, as depicted in Fig. 43.

Depending on the purity, the recrystallization temperature for highly purified copper and commercially pure copper ranges from $80\text{ }^{\circ}\text{C}$ to $300\text{ }^{\circ}\text{C}$. If a heavily cold worked copper is given enough time, it can even recrystallize at room temperature. Alloying elements raise the recrystallization temperature as shown in Fig. 44. 0.02 wt% Zr raises the recrystallization temperature to $540\text{ }^{\circ}\text{C}$ (not shown here), while the effect of, e.g., Zn is low.

As mentioned before, the recrystallization temperature strongly depends on the purity of the material, for which reason the recrystallization temperatures discussed before differ. As shown in Table 7 (DKI, 1982), the recrystallization temperature in oxygen-free copper with just 20 ppm additions range between $140\text{ }^{\circ}\text{C}$ and $222\text{ }^{\circ}\text{C}$, and in oxygen containing copper the range is up to $260\text{ }^{\circ}\text{C}$.

Grain growth

With continued heating, the larger [recrystallized grains](#) grow at the expense of other smaller recrystallized grains, with the result that the grain size increases. In most theories of grain boundary motion, the growth rate is usually expressed by a product of the grain boundary mobility of the rate-determining process and the driving force. The increase of the average grain diameter during isothermal heat treatments can be described by an empirically established time law. Assuming that the mean radius of curvature of the grain boundary R is proportional to the diameter of the grain D , and that the mean grain boundary velocity v is proportional to the time variation of the grain diameter dD/dt , the law can be formulated as follows:

$$\frac{dD}{dt} = C_1 \frac{\gamma}{D} \quad C_1 \sim \exp \left[-\frac{Q}{kT} \right]$$

From this, γ is the surface energy, follows by integration:

$$D^2 - D_0^2 = C_2 \gamma t$$

Assuming that the grain size has already increased considerably ($D \gg D_0$), the following applies:

$$D = C \cdot t^n$$

Here, $n = 0.5$, but this has been observed experimentally only for pure elements and for annealing temperatures close to the melting point. It was shown experimentally that the exponent n depends on purity and temperature and ranges from 0.1 to 0.5. It is obvious that the grain boundary mobility is higher for pure materials and secondary phases slow down the motion of grain boundaries. In consequence, oxide dispersion strengthened coppers, such as, e.g., Cu-Al₂O₃, are resistant to grain growth and, therefore, are suitable for high temperature applications.

Annealing textures

The texture of copper cold rolled 97% at room temperature and recrystallized at 200 °C consists almost entirely of cube texture and its twins. Other textural components of copper, rolled at lower temperatures and recrystallized at 400 °C, are indicated in [Table 8](#). The recrystallization texture of copper rolled at -196 °C is very similar to the recrystallization texture of cold-rolled brass.

The transition from copper-type [recrystallization texture](#) to the brass-type texture depends on the [stacking fault energy](#) of the alloy. The strength of the cube texture is reduced by light rolling reductions, large grain sizes, and low [recrystallization temperatures](#).

Table 8 Texture components of copper, rolled, and recrystallized at 400 °C.

Component	Percentage of texture		
	−80 °C	−140 °C	−196 °C
$(2\ 1\ 4)\left[\bar{5}\ \bar{2}\ 3\right]$	0	21.4	57.4
$(3\ 1\ 0)[0\ 0\ 1]$	0	8.1	21.3
$(1\ 0\ 0)[0\ 0\ 1]$	94.5	60.4	12.8

Anisotropy

The anisotropy of plastic behavior of sheet material is conventionally documented by the Lankford parameter or *R*-value which is defined by the ratio of contractile strains during a [tension test](#),

$$R = \frac{\varepsilon_w}{\varepsilon_t}$$

where *w* and *t* denote the width and thickness directions in a tension test. Because *R* changes with the direction of the [tensile axis](#), it is common to measure the values at 0°, 45°, and 90° to the rolling direction and to define an average $\bar{R}$ as

$$\bar{R} = \frac{R_0 + 2 R_{45} + R_{90}}{4}$$

Like all [f.c.c. metals](#), copper and [copper alloys](#) have *R*-values considerably <1.0. For annealed copper, typically, $R_0 = 0.9$, $R_{45} = 0.4$, $R_{90} = 0.9$, and $\bar{R} = 0.6$ or 0.7 and for annealed 70:30 brass, typically, $R_0 = 0.9$, $R_{45} = 0.9$, $R_{90} = 0.8$, and $\bar{R} = 0.9$. The cube texture component lowers R_{45} considerably, while components with $\{1\ 1\ 1\}$ parallel to the sheet raise the *R*-values.

Corrosion

Many of the applications of copper and copper-based alloys depend on their generally good [corrosion resistance](#). Due to its standard electrochemical potential +0.34 V for Cu/Cu²⁺ and +0.52 V for Cu/Cu⁺, copper is chemically classified as noble metal, hence is in not oxidizing acids corrosion resistant.

Environments in which copper is susceptible to corrosion attack include certain soft, low-pH well waters, oxidizing acids, ammoniacal solutions, amines, cyanides, nitrates and nitrites, oxidizing heavy metal salts (formation of complex films/compounds), and certain sulfites. The corrosion of copper can also occur by specific microbiologic agents.

Depending on the use condition of the copper material (media, temperature, pH, velocity, etc.), the type and appearance of the corrosion can strongly differ ([Table 9](#)).

A few specific forms of corrosion are given below. One is [pitting corrosion](#) in which the attack is very localized. Pitting attacks cause much more damage than the same amount of metal loss uniformly spread over the corroded surface. A second type of corrosion is [dezincification](#) of brasses containing >15% Zn. Both copper and zinc atoms go into solution, but copper then

Table 9 Types of corrosion according to the conditions.

Surrounding medium	Corrosion type	Corrosion type acc. to the appearance

precipitates as a porous plug. Fig. 45 shows the effect of composition on the tendency to pitting and dezincification. An example of dezincification is shown in Fig. 46.

Brass containing $\geq 15\%$ Zn is susceptible to stress corrosion or season cracking. It occurs only when the brass is under tensile stresses and specific environments. For brass, ammonia is the most common agent. Fig. 47 shows examples of stress-corrosion cracking of brass. The propensity to stress corrosion increases with zinc content and temperature as shown in Fig. 48. Removal of residual stresses by stress-relief anneals is sufficient for many applications.

Hydrogen sickness

Hydrogen is not a problem for most copper alloys. However, if tough-pitch copper containing Cu_2O is exposed to hydrogen at high temperatures, severe embrittlement and crack formation is observed. This water vapor embrittlement is caused by hydrogen reduction of copper oxide inclusions and the formation of water $2\text{H} + \text{Cu}_2\text{O} \rightarrow \text{H}_2\text{O} + 2\text{Cu}$. Water is insoluble in copper, both in liquid and gaseous form, which forms pressurized bubbles and then causes fracture—typically at grain boundaries. At temperatures above the critical temperature for water, the steam pressure generated by the reaction exceeds the strength of copper and cause the grains to be literally forced away from each other. This can happen during casting, welding and heat treatments. Hydrogen formed in humid atmosphere and diffused into the metal. Further, the solubility of hydrogen, like other gases, is much greater in liquid copper than solid copper. Fig. 49 shows the solubility of hydrogen in copper and copper–aluminum alloys (Flinn, 1963). Alloying with aluminum and some other elements decreases the solubility.

Once the copper contains oxides, any contact to a hydrogen-containing atmosphere must be avoided at high temperatures. Problems relating to the occurrence of water vapor embrittlement can be avoided if (i) alloys chosen for hydrogen service are free of oxide inclusions, (ii) alloys contain sufficient amounts of deoxidizing elements, or (iii) alloys are not annealed/treated in hydrogen atmosphere.

Conclusion

Global copper refinery production amounts 24 Mt/a. One third of the total supply comes from recycling. Among the elements copper has the second-best conductivity, which is also reflected by the good conductivities of most copper alloys, ranging from 30 to 59 $\text{M}\Omega\text{m}^{-1}$ and 250 to 400 WmK^{-1} , respectively. Single-phase copper alloys are well deformable via dislocation slip ($\{111\}$ $\langle 110 \rangle$) and in the case of low temperatures and/or low stacking fault energies via deformation twinning. The properties of copper strongly depends on the impurities, as, e.g., the conductivity is very sensitive to alloying and the recrystallization temperature rises from 140 °C to 250 °C by the addition of 20 ppm phosphorous, which is often added for deoxidation. Copper alloys are strengthened by various hardening mechanisms and can show a valuable combination of strength and conductivity of 1.4 GPa and approx. 80% IACS. Certain copper alloys are made for use at high temperatures, showing a softening temperature of approx. 500 °C in the case of CuCrZr. Brass and bronze are used due to their tuneable excellent structure-property relationships, including high strength, good formability, good corrosion resistance, and good wear resistance. Well established as well as novel processing techniques are presented alongside with their potential of widening the field of application of copper and its alloys.

Introduction

Titanium and titanium alloys offer a unique combination of physical and mechanical properties that makes titanium an excellent choice for applications that require high strength at temperatures below 550°C, good stiffness (104–133 GPa), toughness, and corrosion resistance. Another desirable characteristic of titanium is its relatively low density of 4.54 g cm⁻³, which is between iron (7.87 g cm⁻³) and aluminum (2.70 g cm⁻³). The high specific strength along with good corrosion resistance makes titanium an enabling material in the aerospace industry (e.g., airframe components, rotors, and compression blades in jet engines), and it is important in the growing biomedical engineering field due to its biocompatibility with living tissues. Titanium alloys have historically been too expensive for the auto industry, but titanium alloys have been recently used for exhaust systems, valves, and springs (its high-yield strength and moderate modulus value gives titanium alloys tremendous elastic resilience). Titanium aluminide intermetallic alloys are likely to become important in the future, due to their lower density and superior high-temperature capabilities.

Titanium ranks ninth as the most plentiful elements, and is the fourth most abundant structural metal in the Earth's crust exceeded only by aluminum, iron, and magnesium. Despite this abundance, the difficulty in processing titanium makes it expensive (~\$50/kg for Ti, compared to \$4/kg for Al and \$1/kg for Fe); yet it is a strategic metal due to which its corrosion resistance and specific strength outweigh its high cost. The cost is likely to drop in the next decade, as new processing methods that reduce the energy requirements and allow continuous processing are scaled up.

The crystallography is considered first, to establish how phase transformations between low- and high-temperature crystal structures occur. From this, the rationale and the complexity surrounding alloying and processing strategies can be appreciated. Finally, a few problematic issues associated with titanium alloys are noted.

Crystallographic Structure of Phases in Titanium Alloys

Titanium exists in two allotropic crystal forms, α , which is a hexagonal structure with a c/a ratio of ~ 1.59 (slightly squashed compared to the close packed ratio of 1.63), and β , which has the body-centered cubic (b.c.c.) crystal structure. In pure titanium, the α -phase is stable up to the β transus temperature (β_T), 883°C. The α -phase is transformed upon heating above 883°C to the b.c.c. β -phase. The idealized orientation relationship between α (thin lines) and β (dashed lines) is illustrated in Figure 1. However, the actual lattice spacings for α and β do not match perfectly. Figure 2 shows how the atomic positions of these phases are related to each other based on a common origin using lattice constants from a Ti–6Al–4V alloy. With heating, the $\alpha \rightarrow \beta$ transformation requires lattice strains of $\sim 10\%$ expansion along $[2\bar{1}\bar{1}0]_\alpha$ to become a $[100]_\beta$ direction, $\sim 10\%$ contraction along the $[01\bar{1}0]_\alpha$ to become $[01\bar{1}]_\beta$, and $\sim 1\%$ contraction along $[0001]_\alpha$ that becomes $[01\bar{1}]_\beta$. Due to this imperfect geometrical relationship, one of the two

Figure 1 Idealized orientation relationship between α , β , and α'' crystal structures.

Figure 2 Atomic lattice positions of the α , β , and α'' crystal structures.

$\langle 111 \rangle_\beta$ directions in the $\{110\}$ plane will be rotated $\sim 5^\circ$ to align itself with one of the $\langle \bar{2}110 \rangle_\alpha$ directions, leading to six possible variants of β from one α orientation, as shown in Figure 3a. This means that two β variants can be misoriented from another by $\sim 10^\circ$. Thus, β variants arising from one parent α crystal can be misoriented from each other by $\sim 10^\circ$, 50° , 60° , or 70° rotation about a $\langle 011 \rangle_\beta$ axis (a prior $\langle 0001 \rangle_\alpha$ axis).

With the reverse $\beta \rightarrow \alpha$ transformation upon cooling, a $\langle \bar{2}110 \rangle_\alpha$ vector can align with one of the two $\langle 111 \rangle_\beta$ directions on each of the six $\{110\}$ planes in the β -phase. Since the angles between $\{110\}_\beta$ planes are either 60° or 90° , the c -axes of daughter α can

Figure 3 (a) Possible β {0 1 1} plane orientations based upon parent α during $\alpha \rightarrow \beta$ transformation, and (b) two possible α orientations based upon parent β during $\beta \rightarrow \alpha$ transformation.

point in as many as six directions, and each direction has two variants that are rotated $\sim 10^\circ$ about the c -axis. An example of a 90° misorientation from the same parent β crystal is shown in Figure 3b.

Although there are 12 variants of the α orientation possible for each parent β orientation, most prior β grains will only choose a few of the 12 α variants during the α - β transformation process. Recent research has shown that the preferred transformation variants are those that have higher populations of dislocations present on $\{110\}_\beta$ planes. Therefore, it is possible to control the transformation process by controlling the dislocation density in the β -phase. The dislocation density depends on dislocation generation (plastic deformation) and annihilation (recovery) processes that are sensitive to prior deformation history, heating rates, and time at temperature. The understanding of what controls variant selection is just emerging, and it is likely to be exploited profitably in the coming decade to allow the manufacturing processes to be designed to achieve optimized properties for a given application.

In addition to α - and β -phases, there are a number of subtle variations, including α' and α'' martensites that may form during quenching, and ordered phases such as α_2 - and ω -phases. With quenching, there is no opportunity for diffusional segregation of alloying elements; so the resulting hexagonal supersaturated α' has lattice constants slightly different from equilibrium α . The α'' -phase has an orthorhombic crystal structure, which is outlined in bold lines in Figure 1. This crystal structure is between the α and the β crystal lattice (Figure 2). The α_2 -phase (Ti_3Al) is an ordered version of the hexagonal lattice with Al atoms spaced regularly on the hexagonal lattice, which increases the resistance to dislocation motion. There has been much interest in ordered orthorhombic intermetallic Ti-Al-Nb alloys in the past decade. The ω -phase is a different hexagonal ordered-crystal structure that could form in prior β -regions after long-term aging or in α -regions after stress-induced transformation from $\alpha \rightarrow \omega$. Ordered phases resist dislocation motion, which can increase the strength, but the continuous ω -phase is known to reduce the ductility and facilitate crack nucleation.

Figure 2 shows that the atomic arrangement of the α -, α' -, and β -phases are very similar; but small differences in atomic position lead to different crystal structures that have significantly different properties. Thus, phase boundaries in Ti alloys are typically coherent or semi-coherent. These phase boundaries are quite easily observed in polished and etched microstructures, often giving the impression of a fine grain size, but it is important to realize that the domains of similar orientations are often much larger than they appear, and these “invisible” mesotextural features can account for early dwell fatigue crack nucleation.

Unlike steels, the martensitic transformations in titanium result in small volume changes and modest shears, but the paradigm of using martensitic transformations in steels to manipulate microstructures and properties is also used in titanium alloys, though the details are completely different (e.g., α'' is softer than α). Ordered intermetallic alloys based on Ti_3Al and TiAl can also be manipulated with similar strategies as those used in titanium alloys, but again, the details differ. The technology of titanium alloys is highly dependent on the ability to control the phase transformation from the β - to the α -phase using strategic alloying and heat treatment history, which gives titanium alloys flexible and designable properties similar to that possible with steels.

Effects of Crystal Orientations on Mechanical Properties

The hexagonal crystal structure has considerable elastic and plastic anisotropy, which are strongly affected by processing history. Young's modulus is highest (143 GPa) along the c -axis, and lowest (104 GPa) in any direction in the basal plane. Titanium deforms with eight slip and twinning systems are illustrated in Figure 4. Each of these systems require different critical resolved shear stresses to operate, making the plastic deformation process much more complicated than cubic metals. Prism slip in $\langle a \rangle$ directions is the easiest, leading to plastic deformation that leaves the crystal dimension along the c -axis and the c -axis orientation unchanged. The next easiest slip system is basal slip in $\langle a \rangle$ directions, which also does not change the dimension of the crystal along the c -axis, but it causes crystal rotation about a prism plane normal axis. It is possible to have $\langle a \rangle$ slip on pyramidal planes as well.

To change the crystal dimension along the c -axis, twinning or $\langle c+a \rangle$ slip on pyramidal planes is required, but the critical resolved stress for $\langle c+a \rangle$ slip is high, so twinning systems are usually more easily activated. Consequently, Ti crystals are intrinsically hard when stressed along the c -axis. Furthermore, the relative strengths of these deformation systems change with temperature, for example, twinning does not occur at elevated temperatures. Consequently, the distribution of crystal orientations can have a large impact on both elastic and plastic properties. Even pure titanium behaves like a composite material; depending on the crystal orientation with respect to the resolved shear stresses, any crystal can be either hard or soft. In Figure 5, shades of gray represent the Taylor factor (proportional to the plastic flow stress of the crystal) in a rolled plate deformed in uniaxial tension.

Figure 4 (a) Prism slip, (b) basal slip in the $\langle a \rangle$ direction, (c) $\langle a \rangle$ slip, (d) $\langle c+a \rangle$ slip on pyramidal planes, and (e–h) twinning systems; all types have 6 systems. Only $\langle c+a \rangle$ slip or twinning causes a change in crystal dimension in the c direction. Arrows illustrate axis of crystal rotation due to slip; only prism slip does not change the orientation of the c -axis.

The Classification of Titanium Alloys

Titanium alloys are classified according to the phases present within their microstructure. Alloys consisting of mainly α -phase are called α -alloys, but if small amounts of β -phase are present, the alloy is classified as a near- α alloy. Alloys consisting of a mixture of both α - and β -phases are termed α - β alloys. Finally, titanium alloys that have the majority of β -phase at room temperature are called β -alloys. Figure 6 shows the effects that several important alloying elements have on the phase diagram, indicating that the equilibrium between α , $\alpha+\beta$, and β phase fields (α and β transus lines) are highly sensitive to alloy composition. Aluminum is one of the most important alloying elements because it is a potent solid-solution strengthener and it reduces the density, so it is found in virtually all titanium alloys. Ti_3Al (α_2) forms with more than 6 wt.% Al, which can strengthen, but also embrittle the alloy. Molybdenum and vanadium are the two most popular β -stabilizing additives, which also provide strengthening of the β -phase. Tin

Figure 5 Rolled plate (rolling direction and plate normal are indicated) SEM and Orientation Imaging Microscopy Taylor factor maps before (inset) and after annealing above β transus, followed by controlled slow cooling. Taylor factor was computed based upon uniaxial deformation in the rolling direction with CRSS ratios of 0.7:1:3 for prism:basal:pyramidal $\langle c+a \rangle$ slip. (Images obtained at the Air Force Research Laboratory, WPAFB, OH.)

and zirconium are the only two alloying elements used which have neither an α -stabilizing nor β -stabilizing effect on the crystal structure (Figure 6a), but both provide solid-solution strengthening to the α -phase; also, Sn is known to improve weldability. All other elements either stabilize the α - or β -phase, as summarized in Table 1.

The aluminum equivalent and molybdenum equivalent equations (in wt.%) are used to describe the degree of stability of the α - and β -phases, and to define what class an alloy is in. Oxygen and nitrogen are potent α -stabilizers, and iron is the most potent β -stabilizer:

$$\begin{aligned} Al_{\text{equiv}} &= \%Al + \frac{1}{3}(\%Sn) + \frac{1}{6}(\%Zr) + 10(\%O) \\ Mo_{\text{equiv}} &= \%Mo + 0.67(\%V) + 2.9(\%Fe) + 1.6(\%Cr) - \%Al \\ O_{\text{equiv}} &= \%O + 2(\%N) + 0.67(\%C) \end{aligned}$$

Commercially Pure Titanium; 99–99.5% Ti

Commercially pure (CP) titanium is considered an α -alloy, because the α -phase is the only phase present. Oxygen is the main alloying element that determines the grade and strength of the alloy (Figures 6b and 7). CP titanium has lower strength than other alloys, but it is the alloy of choice for applications requiring corrosion resistance, and it has better elevated temperature creep resistance, and is less expensive than the other titanium alloys. Figure 7 shows how the strength and hardness increase with interstitial element concentration. Since oxygen is the main alloying element in CP titanium, the O_{equiv} describes the strengthening effect of the interstitial elements O, N, and C. Each 0.1% O_{equiv} increases the strength of unalloyed titanium by ~ 120.5 MPa.

Near α and α Titanium Alloys; $Al_{\text{equiv}} < 8$ and $Mo_{\text{equiv}} < 1$

Alpha titanium alloys are primarily used in the chemical and processes engineering industry. These applications require excellent corrosion resistance and ductility. Aluminum is the most important alloying element in order to stabilize α -phase, add strength, and lower the density (Figure 6b, Table 2). Ti-5Al-2.5Sn is the most commonly used α alloy, and like most α alloys it cannot be age-hardened, but it does have excellent weldability.

Near- α Titanium Alloys; $6 < Al_{\text{equiv}} < 10$ and $Mo_{\text{equiv}} < 2$

Near- α alloys are ideal for high temperature applications ~ 500 – 550°C , where its excellent creep resistance can be combined with higher strength due to a small amount of dispersed β -phase. Small amounts of molybdenum and vanadium are added to retain some β -phase at room temperature. Ti-8Al-1Mo-1V is the most commonly used near- α alloy, however the high aluminum content can cause stress corrosion cracking (SCC) problems; therefore, most alloys used today are limited to 6 wt.% Al to avoid SCC problems. This alloy has good weldability, but a limited degree of hardenability due to a small amount of β -phase.

Figure 6 Exemplary phase diagrams for elements that have (a) neutral, (b) α stabilizing, (c) β stabilizing, and (d) β eutectoid stabilizing effects. (Adapted from Smithells Metals Reference Book, 7th edn., 1992, London: Butterworth. McCullough C, Valencia JJ, Levi CG, and Mehrabian R (1989) Phase equilibria and solidification in Ti–Al alloys. *Acta Metallurgica* 37(5): 1321–1336, for update of Ti–Al system.)

α – β Titanium Alloys; $5 < Al_{equiv} < 10$ and $2 < Mo_{equiv} < 8$

The α – β alloy Ti–6Al–4V is the most popular of all titanium alloys, representing more than 50% of the titanium market (Figures 6b and 6c). The α – β alloys can be solution heat-treated, quenched, and aged to medium-/high-strength levels and have good formability, but the creep resistance and weldability are lower than the α and near- α alloys, primarily due to the presence of the β -phase, which has a much higher diffusivity and more slip systems.

β Titanium Alloys; $Al_{equiv} < 6$ and $Mo_{equiv} = 15–30$ (Metastable β), > 30 (Stable β)

The β titanium alloys are heat treatable, to achieve the highest strength levels of the five types of titanium alloys (Figures 6c and 6d). The high strength arises from precipitation of very fine α -phase during an aging heat treatment. The b.c.c. crystal structure also gives

Table 1 Effects of alloying elements

Alloying element	Range (wt.%)	Effect on structure and properties
Aluminum, Al	2–7	α -Stabilizer, solid solution strengthener, reduces density, improves oxidation resistance
Carbon, C	0.05–0.1	α -Stabilizer, interstitial element
Chromium, Cr	2–12	β -Eutectoid stabilizer
Cobalt, Co		β -Eutectoid stabilizer
Copper, Cu	2–6	β -Eutectoid stabilizer, improves weldability, α and β strengthener
Hydrogen, H	0.008–0.02	β -Eutectoid stabilizer, interstitial element
Iron, Fe		β -Eutectoid stabilizer
Manganese, Mn		β -Eutectoid stabilizer
Molybdenum, Mo	2–20	β -Isomorphous stabilizer, moderate solid solution strengthener of β phase
Nickel, Ni		β -Eutectoid stabilizer
Niobium, Nb		β -Isomorphous stabilizer, known to improve oxidation behavior of Ti alloys, moderate solid solution strengthener of β phase
Nitrogen, N	0.015–0.07	α -Stabilizer, interstitial element
Oxygen, O	0.1–0.4	α -Stabilizer, interstitial element, strengthens α phase
Silicon, Si	0.05–1	β -Eutectoid stabilizer, Si atoms tend to segregate at dislocations and thus effectively prevent dislocation climb, improving creep resistance, also strengthens α phase
Tantalum, Ta		β -Isomorphous stabilizer
Tin, Sn	2–6	Neutral stabilizer, improves weldability, solid solution strengthener of α phase
Vanadium, V	2–20	β -Isomorphous stabilizer, moderate solid solution strengthener of β phase
Zirconium, Zr	2–8	Neutral stabilizer, solid solution strengthener of α phase, Zr also tends to homogenize fine silicide precipitates

good formability properties prior to heat treatment. Beta titanium alloys contain large amounts of alloying elements such as Mo, Cr, V, and Fe which are needed to stabilize the β -phase. The high degree of alloying elements makes β alloys the densest of the five alloy types (Table 2).

Tables 2–4 provide further details, using normal font to identify CP, italics to identify near- α and α alloys, bold italics to identify α - β alloys, and bold to identify β alloys. Table 2 is sorted by density to illustrate the influence of alloying. Table 5 describes weldability issues, and Tables 3 and 4 describe heat treating methodologies, which are discussed next.

Heat Treating of Titanium Alloys

Titanium and titanium alloys are heat treated for a number of reasons: to reduce residual stresses from the many different fabrication processes (stress relieving), to obtain optimum combinations of ductility, machinability, and dimensional stability (annealing), to increase strength (solution treating and aging in α - β and β alloys), and finally to optimize specific properties such as fracture toughness, fatigue strength, and high-temperature creep resistance. In general, a heat treatment is used to rearrange phase-volume fractions, phase boundaries in strategic ways. A quench from high temperature is commonly used to provide a

Table 4 Heat treating of α - β alloys

Heat treatment designation	Heat treatment cycle	Microstructure
Duplex anneal	Solution treat at 50–75°C below $T(\beta)$, air cool and age for 2–8 h at 540–675°C	Primary α , plus Widmanstätten α - β regions
Solution treat and age	Solution treat at $\sim 40^\circ\text{C}$ below $T(\beta)$, water quench(a) and age for 2–8 h at 535–675°C	Primary α , plus tempered α' or a β - α mixture
Beta anneal	Solution treat at $\sim 15^\circ\text{C}$ above $T(\beta)$, air cool and stabilize at 650–760°C	Widmanstätten α - β colony microstructure
Beta quench	Solution treat at $\sim 15^\circ\text{C}$ above $T(\beta)$, water quench and temper at 650–760°C for 2 h	Tempered α'
Recrystallization anneal	925°C for 4 h, cool at 50°C h^{-1} to 760°C, air cool	Equiaxed α with β at grain-boundary triple points
Mill anneal	α - β Hot work plus anneal at 705°C for 30 min to several hours and air cool	Incompletely recrystallized α with a small volume fraction of small β particles

In more heavily β -stabilized alloys such as Ti-6Al-2Sn-4Zr-6Mo or Ti-6Al-6V-2Sn, solution treatment is followed by air cooling. Subsequent aging causes precipitation of α -phase to form an α - β mixture.

Table 5 Welding of titanium alloys

Alloy type	Condition	Description
Unalloyed titanium	Annealed	Welding of cold-worked alloys anneals the HAZ and negates any strength produced by cold working
Alpha titanium alloys	Annealed	Ti-5Al-2.5Sn, Ti-6Al-2Sn-4Zr-2Mo, Ti-5Al-5Sn-2Zr-2Mo, Ti-6Al-2Nb-1Ta-1Mo, and Ti-8Al-1Mo-1V are always welded in annealed condition
Alpha-beta titanium alloys	Annealed or solution-treated and partially aged	Low weld ductility of most α - β alloys is caused by phase transformation in the weld zone or HAZ
Metastable beta titanium alloys	Annealed or solution heat treated	In as-welded condition, welds are low in strength but ductile; to obtain full strength the alloys are welded in annealed condition, the weld is cold worked by shot peening or planishing, and the weldment is then solution treated and aged
Weld type	Thickness range	Description
Gas-tungsten arc weld (GTAW)	Base metal up to 2.5 mm, for thicker base metal filler metal is required	
Gas-metal arc weld (GMAW)	More than 3 mm to greater than 13 mm	Applied using pulse current or spray mode and is less costly than GTAW
Plasma arc welding (PAW)	Plate up to 13 mm, filler metal may be used	Faster than GTAW and can be used on thicker sections
Electron-beam welding (EBW)	Plates 6 mm to more than 76 mm	Used in aircraft and aerospace industry for producing high quality welds; performed in high vacuum atmosphere therefore low contamination of weldment
Laser-beam welding (LBW)	Base metal usually cannot exceed 13 mm	
Friction welding (FRW)		Useful for joining tube, pipe, or rods
Resistance welding (RW)		Used to join titanium sheet by spot welds or continuous seam welds, also used to weld titanium sheet to dissimilar metals
Fluxes	N/A	Fluxes cannot be used because they combine with titanium to form brittleness and may reduce corrosion resistance

Excerpted from (1990) Welding brazing and soldering. *ASM Metals Handbook*, vol. 6, pp. 783–786. Metals Park, OH: ASM International.

thermodynamic driving force for nanoscale rearrangement at lower aging temperatures. More recently, benefits of rapid heating into the β -phase field to obtain desirable microstructures have been described. Standard practice is identified in [Tables 3 and 4](#), and the preferred phase for alloying elements is in [Table 1](#). However, alloy element local concentration is highly dependent on the history of the phase volume fraction and locations of phase boundaries in space and hence, on all prior heat treating and working history. For this reason, the same heat treatment on materials with different prior history can cause considerable variability in resulting properties.

Unalloyed α titanium alloys can be stress relieved and annealed, but cannot be heat treated to increase their strength. When the heat treatment of titanium alloys involves heating to temperatures near the β transus, it is important that T_β is known for each specific alloy. [Table 3](#) illustrates how the β transus temperature (β_T) depends on alloy composition.

Stress Relieving

Stress relieving (SR) is used to remove residual stresses from prior fabrication steps, or even prior heat treatments. Unbalanced residual stresses can result in part distortion, and cause problems in those alloys susceptible to hydrogen embrittlement. SR can result in aging of all alloy types, α can be aged by α_2 precipitates, and if metastable β is present, α precipitation that provides strengthening can occur. For α and α - β alloys, the SR temperature will be in the range of 480–815°C, and if these alloys were β -annealed, more rearrangement of phase boundaries is needed and the SR temperature should be increased by $\sim 55^\circ\text{C}$. When stress-relieving β alloys, care must be taken to avoid interfering with the final age-hardening treatment. If a β alloy has not been heat treated, the SR temperature should be substantially below the β_T to prevent preferred α precipitation in grain boundaries (which embrittles the material). If the β alloy is in its final age-hardened condition, the SR temperature should be at or below the aging temperature to prevent strength reduction.

Annealing

Annealing is similar to SR but usually done at higher temperatures. The annealing of titanium and titanium alloys serves primarily to increase fracture toughness, room temperature ductility, dimensional stability, and high-temperature creep resistance. This is often the final heat treatment for α and α - β alloys, as it yields a good balance of properties. Care must be taken when using β alloys in the annealed condition in service temperatures up to 400°C, which could result in embrittlement, and service temperatures in the range of 400–600°C could age-harden the β alloy, resulting in a strength increase at the expense of ductility. Alpha and α - β alloys are typically annealed in the temperature range of 700–900°C, while β alloys are normally annealed in the temperature range of 690–815°C.

There are four commonly used annealing treatments, mill annealing (MA), duplex annealing (DA), recrystallization annealing (RA), and β annealing (BA). MA is a general-purpose heat treatment given to all mill products, but it is not a full anneal and the material may retain effects of prior working processes. DA is used for α and α - β alloys; it involves an initial anneal high in the α/β -phase field to generate significant fractions of both α and β with small grain/phase sizes near 10 μm , followed by an MA to provide thermal stability in the prior β regions. DA improves creep resistance and fracture toughness (resistance to crack nucleation) of the material. An RA is done at a temperature high enough in α/β -phase field to ensure recrystallization. It is then slowly cooled to form a high-volume fraction of equiaxed α with islands of retained β at triple points, and some interfacial β at α/α boundaries. RA provides high-damage tolerance properties (fracture toughness, crack growth resistance) that are crucial for fracture critical applications. Finally, BA is done at temperatures above the β_T , leading to a large grain size followed by a subsequent MA (Figure 5 shows how a BA converted a small grain size DA microstructure into large prior β grains that were transformed into several α variants during slow cooling). For α and α - β alloys, BA maximizes the damage tolerance properties, since resistance to crack propagation is best when there are fewer grain boundaries.

Solution Treating

Solution treating (ST) is used to transform a desired amount of α - to β -phase in near α and α - β alloys, by heating the material to a temperature near β_T and then cooling strategically to produce a higher ratio of β -phase in a desired morphology. Beta alloys are normally solution treated above the β_T (700–815°C), while α and α - β alloys are normally solution treated slightly below the β_T (850–1000°C) (Table 3). For most β alloys, the object of ST is to retain 100% β -phase upon quenching, so that upon subsequent aging, decomposition of the metastable β -phase occurs to generate second-phase precipitates that provide high strength.

Quenching

The rate of cooling from the ST temperature strongly affects the strength of the material. Slow cooling rates allow diffusion to occur, resulting in decomposition of the β -phase and may prevent effective strengthening during the aging process. Also the quench delay, which is the time from which the material is removed from the furnace and subsequently placed into the quenching media, can affect properties. Longer quench delays can lower strength; this reduced strength is ascribed to the formation of coarse acicular α prior to immersion in quenchant. Alpha-beta alloys are typically quenched in water, a 5% brine solution, or a caustic soda solution because the rate is sufficient to retain the β -phase obtained by ST. For highly β -stabilized alloys and small sections, an air or fan cooling may be adequate.

Aging

Aging is the final heat treatment step needed in order to achieve high-strength levels. Aging causes the decomposition of the supersaturated β -phase retained upon quenching, through α -precipitation within the β -matrix. Martensites also decompose in a manner that sharpens interfaces or boundaries that provide strengthening. The aging temperature controls the size and volume fraction of the α -precipitates, and determines the final strength of the material. Aging at or near the annealing temperature results in overaging, which is desirable if good toughness and dimensional stability are needed with only a modest increase in strength. For α

and α - β alloys, aging is usually done in the temperature range of 480–605°C, and β alloys are typically aged in the temperature range of 425–595°C.

Suggested heat treatments for various titanium alloys are listed in Tables 3 and 4. It is also important to note that not all heat treatments are applicable to all titanium alloys, because some alloys are designed for specific purposes, for example, Ti-5Al-2Sn-2Zr-4Mo-4Cr (Ti-17) and Ti-6Al-2Sn-4Zr-6Mo are designed for strength in heavy sections, Ti-5Al-2.5Sn and Ti-2.5Cu, for weldability, Ti-6Al-2Sn-4Zr-2Mo and Ti-6Al-5Zr-0.5Mo-0.2Si, for creep resistance.

Welding of Titanium Alloys

Table 5 provides relevant details for welding titanium alloys. Unalloyed titanium and α alloys are weldable. These alloys are typically welded in the annealed condition, and have good weldability because they are insensitive to heat treatments. Alpha-beta alloys and weakly β -stabilized alloys are also weldable, but should be welded in the annealed or solution-treated conditions prior to aging heat treatments. Most β alloys can be welded in annealed or solution-treated condition, but subsequent aging can cause the weld to become brittle. Most strongly β -stabilized alloys are embrittled by welding, since it is not possible to quench a weld (without quenching, second phases precipitate preferentially on grain boundaries).

Challenging and Problematic Issues with Titanium Alloys

Although titanium alloys have many desirable characteristics, they have problematic areas as well. These include their affinity to oxygen, hydrogen pickup, susceptibility to certain types of chemical attack, and damage generation arising from the elastic and plastic anisotropy of the hexagonal crystal structure.

Heat treating can cause contamination due to oxidation that causes an oxygen-rich brittle layer on the metal surface called “ α case.” Unless surface hardening is needed for wear resistance, this α case must be mechanically or chemically removed before the part can be put into service. Another concern is embrittlement due to very low levels of hydrogen, nitrogen, and carbon absorption at virtually every fabrication stage from casting to heat treating. Due to its great affinity to oxygen, alumina (Al_2O_3) cannot be used to machine titanium alloys, so WC tools (typically C-2 grades) are used for turning and face milling, while high-carbide, high-speed steels are appropriate for drilling, tapping, and end milling.

Though CP titanium is highly corrosion resistant, SCC is more likely with increasing alloy content, and in environments with red fuming nitric acid, N_2O_4 , HF, methanol, HCl, and seawater. The susceptibility depends greatly on alloy elements, crystal orientation and misorientations at grain boundaries, and the details of microstructural evolution.

Due to its hexagonal crystal structure, slip in the $\langle a \rangle$ direction is much more facile than other directions, so heterogeneous deformation and shear banding is common. Combinations of working and heat treatment can generate highly preferred crystal orientations, so between the coherent phase boundaries with transformation shears, and the anisotropy of the thermal expansion coefficient (which is 20% higher in the $\langle c \rangle$ than $\langle a \rangle$ directions) substantial residual stresses are common even after a stress relief anneal. Though titanium alloys can be processed for excellent high-temperature creep resistance, room-temperature creep occurs in some microstructures and alloys, and hence dimensional stability can be a problem. To fully optimize material property design for particular applications, control of texture and microstructure with innovative processing strategies requires predictive understanding of the rules for variant selection during the $\alpha \rightarrow \beta \rightarrow \alpha$ transformations, which are not yet well established.

Abstract

High-Entropy Alloys (HEAs) is a revolutionary concept of the alloy design field proposed in 2004. It provides a much greater scope of composition design than ever before. The four core effects of HEAs could lead to good combinations of properties and allow tuning the crystal structures and microstructures of the system. The fundamental physical metallurgy principles of HEAs are different from those of the conventional alloys in many aspects, and the deformation mechanisms of HEAs are particularly interesting to the community. Recently, a new mechanism of strengthening and toughening by high slip-plane density in HEAs has been proposed. Since HEAs possess great potentials for various applications, several types of HEAs have been developed, such as low stacking fault high-entropy alloys (LSF-HEAs), high-entropy superalloys (HESAs), refractory high-entropy alloys (RHEAs), high-entropy metallic glasses (HEMGs), eutectic high-entropy alloys (EHEAs), high-entropy intermetallic compounds (HEICs), and high-entropy Coatings (HE-Coatings). In this article, the basic concept and definition of HEAs are described. Furthermore, the four core effects are reviewed and clarified. The recent progresses of developing LSF-HEAs, HESA, HEMGs, RHEAs, EHEAs, HEICs, and HE-Coatings for potential applications are summarized.

Key points

- Fundamental concepts and developments of HEAs are introduced.
- The four core effects of HEAs are reviewed and clarified.
- The potential applications of HEAs in LSF-HEAs, HESAs, HEMGs, RHEAs, EHEAs, HEICs, and HE-Coatings are summarized.

Introduction

High-Entropy Alloys (HEAs) is a revolutionary concept of the alloy design; it provides a much greater scope of composition design than ever before. The four core effects of HEAs could lead to good combinations of properties and allow tuning the crystal structures and microstructures of the system. Since HEAs possess great potentials for various applications, several types of HEAs have been

developed. In this article, the basic concept and definition of HEAs are described. Furthermore, the four core effects are reviewed and clarified. The recent progresses of developing LSF-HEAs, HESAs, HEMGs, RHEAs, EHEAs, HEICs, and HE-Coatings for potential applications are summarized.

Concepts and definition of high-entropy alloys

The human civilization has been defined by the development and applications of materials, such as stone, bronze, and iron; the development of rudimentary thermo-chemistry allowed the extraction of copper and iron, and led to the Bronze Age and the Iron Age. Cast iron technology in 1620s established the dominance of metal alloys in engineering at that time, followed by the development of steel technology in 1850 and other special alloys such as stellite alloys (mostly cobalt based with additions of Cr, C, W, and/or Mo), permalloys (nickel–iron magnetic alloy), copper–beryllium alloys, aluminum alloys, titanium alloys, magnesium alloys, and superalloys. The materials development in the timeline have been driven by the desire for greater performance; however, since 1950s, the rate of development of new metallic alloys has slowed down. This could be due to the limitation of composition design space based on one major solvent, as well as the competitions from other types of engineering materials.

High-Entropy Alloys (HEAs) is a novel concept in alloy design explored by Professor Jien-Wei Yeh since 1995 (Taiwan). After eight years of research, he and his team published the first five papers on HEAs in 2004 (Yeh et al., 2004a). Different from the conventional alloy design space, which restricts itself to the corner of the phase diagram, Professor Yeh and his group reported a new approach to design alloy by mixing elements in nonequimolar or equimolar proportions, forming multi-principal-component alloys. These new alloys possess higher configurational entropy than those of common commercial alloys which mainly based one element. According to the statistical thermodynamics, Boltzmann's equation can be used to calculate the configurational entropy of a system (Gaskell, 1995; Moore, 1962):

$$\Delta S_{conf} = k_B \ln w \quad (1)$$

where k_B is Boltzmann's constant and w is the number of available energies that can be mixed among the system. For a n -element alloy in the random solution state, the ideal configurational entropy can be expressed as:

$$\Delta S_{conf} = -R \sum_{i=1}^n X_i \ln X_i \quad (2)$$

where R is the gas constant, 8.314 J/K · mol, and X_i is the atom fraction of the i th element.

Based on Eq. (2), we can calculate the configurational entropy per mole for an equimolar alloy in regular solid solution state or liquid state by the following expression as Eq. (3) (Yeh et al., 2004a; Yeh, 2006):

$$\Delta S_{conf} = k_B \ln w = -R \left(\frac{1}{n} \ln \frac{1}{n} + \frac{1}{n} \ln \frac{1}{n} + \dots \frac{1}{n} \ln \frac{1}{n} \right) = -R \ln n \quad (3)$$

The ideal configurational entropies for equimolar alloys ($X_1 = X_2 = \dots = X_n$ in Eq. 2) with different n -elements up to 13 are shown in Table 1. The ΔS_{conf} is increased as the number of elements in the system increases.

Professor Yeh proposed two definitions for HEAs (Yeh, 2013). One expression is based on the composition and shown in Eq. (4), and the other is based on the configurational entropy and shown in Eq. (5).

$$n_{major} \geq 5 \text{ and } n_{minor} \geq 0$$

$$5 \text{ at.\%} \leq X_i \leq 35 \text{ at.\% and } X_j \leq 5 \text{ at.\%} \quad (4)$$

$$\Delta S_{conf} \geq 1.5R \quad (5)$$

where n_{major} and n_{minor} are the number of major elements and minor elements, respectively. X_i and X_j are the atomic percentage of major elements i and minor elements j , respectively.

According to the definition given in Eq. (5), the medium-entropy alloys (MEAs) and the low-entropy alloys (LEAs) can be defined as well based on the configurational entropy (Yeh, 2013). Fig. 1 shows the composition scope of alloys based on the configurational entropy. This demonstrates that the HEAs can extend the design scope greater than those of LEAs and MEAs. Therefore, there should be more room to tune the compositions for a broad range of structures and properties (Yeh et al., 2004a; Huang et al., 2004; Chen et al., 2004).

Table 1 The ideal configurational entropies ($\Delta S_{conf}/R$) for equimolar alloys with different n -elements up to 13 (Yeh, 2013).

n	1	2	3	4	5	6	7	8	9	10	11	12	13
$\Delta S_{conf}/R$	0	0.69	1.10	1.39	1.61	1.79	1.95	2.08	2.20	2.30	2.40	2.49	2.57

Before Prof. Jien-Wei Yeh of Taiwan published the novel concept of “High-Entropy Alloys” in 2004, Professor Brian Cantor of the United Kingdom also carried out similar pioneering work. In 1981, Professor Brian Cantor initiated a research on equi-atomic multicomponent alloys with Alain Vincent (Cantor, 2014); it was found that only $\text{Co}_{20}\text{Cr}_{20}\text{Fe}_{20}\text{Mn}_{20}\text{Ni}_{20}$ possesses a single FCC phase, indicating that all these five elements are mixed into a solid solution. However, this work was unpublished until 2004 except in a thesis at Sussex University. Prof. Brian Cantor found that the total number of phases is always significantly less than the maximum equilibrium number allowed by the Gibbs phase rule and even less than the maximum number allowed under nonequilibrium solidification condition.

Professor Srinivasa Ranganathan of India is another significant scientist who assisted the launch of HEAs technology; Professor Ranganathan contributed to the understanding of the structure of interfaces, quasicrystals, bulk metallic glasses, nanostructured materials, and novel multicomponent alloys. After his communications and discussions about HEAs with Prof. Jien-Wei Yeh, Prof. Ranganathan’s article entitled “Alloyed pleasures – multimetallic cocktails” was published in Current Science in November 2003 (Ranganathan, 2003). This article was the first journal publication mentioning HEAs. In this article, Prof. Ranganathan reviewed three alloy systems, that is, bulk metallic glasses, superelastic and superplastic alloys, and HEAs. Hence, Professor Ranganathan was the first person to introduce Professor Yeh’s high-entropy alloy research to the world. The following section reviews the four core effects of HEA and deformation mechanisms in more details

The four core effects and related theories of high-entropy alloys

In the field of physical metallurgy, the relationships between composition, processing, structures, and properties are investigated and correlated (Reed-Hill, 1994). The design guideline of HEAs has been laid out by four core effects (Yeh, 2006; Murty et al., 2014). These are (1) high configurational entropy effect for thermodynamics (2) sluggish diffusion for kinetics v, (3) lattice distortion effect for structure, and (4) the cocktail effect for properties. Fig. 2 illustrates how four core effects influence the physical metallurgy of HEAs (Biswas et al., 2020); even until recently, these four core effects of HEAs are still under passionate debate.

High entropy effect

High entropy effect is associated with the enhanced thermodynamic stability of solid solution phases (Yeh, 2013), and the configurational entropy is the main consideration. The other entropy terms involved such as vibrational, electronic, and magnetic are relatively small and often neglected for convenience. According to the second law of thermodynamics shown in Eq. (6), a system reaches its thermodynamic equilibrium when its Gibbs free energy ΔG_{mix} is the lowest at a given temperature and pressure.

$$\Delta G_{\text{mix}} = \Delta H_{\text{mix}} - T\Delta S_{\text{mix}} \quad (6)$$

where ΔH_{mix} is the mixing enthalpy of the system, T is the given temperature, and ΔS_{mix} is the mixing entropy of the system.

The magnitude of mixing enthalpies with negative values indicates the tendency for the compounds or second phase formation. However, a large configurational entropy in near-equi-molar alloys with 5 or more elements can counterbalance the effect of mixing

Fig. 2 Four core effects of HEAs' influence on physical metallurgy.

enthalpy and promote the formation of solid solutions (SS) phases instead of pure elements segregations or compounds (Miracle et al., 2014). Zhang et al. (Zhang et al., 2008) also proposed the forming trend of disordered SS, ordered SS intermediate phases and bulk metallic glass (BMG) by comparing ΔS_{mix} , ΔH_{mix} , and atomic size difference, and found the significance of entropy effect. Moreover, Yang and Zhang (2012), Yeh (2009), and Guo and Liu (2013, 2011) clearly showed how the thermodynamic phase stability will be influenced by higher entropy, and provided a guideline for SS phase formation. The high entropy effect is definitely the most essential effect of HEAs. It emphasizes that mixing entropy term, which plays a critical role to further decrease the mixing free energy of the random state, could render greater stability for the SS phases of HEAs. This effect of entropy allows alloy designers to control the microstructure in order to design materials with promising properties. Furthermore, Cheng et al. (2017) reported that the mixing entropies of phases in HEAs can be higher than that in conventional alloys, and the higher entropy could counterbalance the strain energy and chemical energy increases due to mixing and guarantee the stable existence of lattice-distorted concentrated solid solutions (CSS).

Sluggish diffusion effect

Sluggish diffusion effect means that the diffusion rate becomes slower in the distorted lattice, and in addition, the rate of phase transformation is slowed down due to required cooperative diffusion of many elements for nucleation and growth of crystals or phases. A more positive enthalpy of formation and an excess amount of mixing entropy are both related to the formation of vacancy in crystalline HEAs (Moore, 1962). Since vacancy is the key control factor of substitutional diffusion, vacancy concentration and its mobility in the whole solute matrix are important diffusion issues in HEA systems. Different from the conventional alloys, either a vacancy or an atom of the HEAs would have a fluctuated diffusion path to migrate and have slower diffusion with higher activation energy. As a result, the phase transformation in HEAs would be slower and tend to form the nanostructure or even amorphous structure due to sluggish diffusion and cooperative diffusion. In other words, sluggish diffusion could better retain the properties of HEAs at elevated temperatures (Tsai et al., 2009; Senkov and Woodward, 2011; Senkov et al., 2011a). Cheng et al. (2017) reported sluggish diffusion phenomena in high-entropy concentrated solid solutions by observing slower phase transformation rate. This could be caused by lattice distortion, which could result in variations of lattice potential energy and higher activation energy along the diffusion path. Fig. 3 shows that atoms in the HEA lattice would experience fluctuated lattice potential energy due to different lattice distortion and coordination bonding along its diffusion path; hence atoms in HEAs lattice need higher activation energy to overcome deeper traps in order to migrate in the path (Gao et al., 2016). The direct evidence of sluggish diffusion in HEAs systems

Fig. 3 Schematic diagram shows the fluctuation of lattice potential energy along the diffusion path for an atom jumping in the lattice. Adapted from Gao MC, Yeh JW, Liaw PK, and Zhang Y (2016) High-Entropy Alloys Fundamentals and Applications, Springer. ISBN 978-3-319-27011-1.

has been obtained by diffusion couple experiment. Tsai et al. (2013) conducted the diffusion experiment on diffusion couples that consisted of single-face-centered cubic Co—Cr—Fe—Mn—Ni systems. For each couple, only the concentrations of two elements were adjusted. The diffusion couples were annealed at various temperatures in order to determine the diffusion profile so that diffusion coefficients of each element and activation energy could be determined. The author measured the temperature dependence of the diffusion coefficients for Cr, Mn, Fe, Co, and Ni in different matrix including FCC pure metals and various stainless steels. The data showed that the diffusion coefficients for Cr, Mn, Fe, Co, and Ni in the HEA system are smaller than in the pure matrix. It is apparent that sluggish diffusion occurred in the HEA. In addition to this nonradiotracer method, radiotracer method has been conducted on CoCrFeMnNi alloy (Vaidya et al., 2016, 2018); an obvious decrease in bulk diffusion rates is confirmed when the homologous temperature is used for comparison. This demonstrates that higher lattice distortion could lead to slower atomic diffusion since homologous temperature used for comparison could reveal the main effect from lattice distortion on diffusion. Interestingly, sluggish diffusion has also been reported recently in the high-entropy ceramic systems (Li et al., 2022; Zhang et al., 2021). Thus, it appears that sluggish diffusion phenomenon is a genuine effect associated with lattice distortion in different high-entropy materials systems.

Severe lattice distortion effect

Lattice distortion caused by solute atoms is well known in traditional physical metallurgy; however, this effect in HEAs is more pronounced since the distortion is at every site and varies from one site to the next, that is, severe lattice distortion. Hence, it would have a profound influence on the properties of HEAs. The lattice distortion is nominally related to differences in atomic size (δ) in the Eq. (7) for multi-element system (Yang and Zhang, 2012).

$$\delta = 100 \sqrt{\sum_{i=1}^n c_i (1 - r_i / \bar{r})^2} \quad (7)$$

where $\sum_{i=1}^n c_i r_i$ and c_i and r_i are the atomic percentage (%) and atomic radius of the i th element (nm), respectively, and $\bar{r}$ is the average radius (nm).

In addition to the atomic size difference, atomic bonding difference between atomic pairs also contributes to the distortion since an atom can have different neighboring atoms and hence has nonsymmetrical bonding with neighbors. However, the actual degree of lattice distortion would be smaller than the nominal difference because some relaxation of atomic configuration would occur in order to achieve smaller overall free energy of the whole alloy. Interactions will occur when dislocations, electrons, phonons, and X-ray beam pass through severe distorted lattice (Gao et al., 2016). Thus, dislocation movement would be more difficult and hence solution hardening could be achieved; electrons and phonons would be scattered, resulting in lower conductivities. X-ray beam would also be scattered remarkably in the distortion lattice and thus result in smaller peak intensity.

Lin et al. (2021) showed how severe lattice distortions' effect could influence mechanical properties in HEAs. Higher solution-hardening rates occurred in concentrated solutions due to high concentrations of lattice distortion sites in the whole-solute matrix (Fig. 4). Fig. 4 illustrates how dislocation lines move smoothly in the lattice of a pure metal (low entropy state), how they are dragged by small number of solutes encountered in the dilute solutions (medium entropy state), and how they are dragged by a large number of solutes encountered in the concentrated solutions (high entropy state). As a result, both the lattice friction and solution hardening are increased to enhance the yield strength of concentrated solid solutions. The authors measured the stress and strain curves of Ni (1A), Ni-2at%W (1A2W), Ni-4atwt%W (1A4W), CrFeNi (3A), and CoCrFeMnNi (5A) alloys and showed that the 3A alloy (CrFeNi MEA) and 5A alloy (CoCrFeMnNi HEA) have significantly higher strength than those of pure and dilute metals, 1A (Ni), 1A2W (Ni-2at%W), and 1A4W (Ni-4at%W), even though the nominal atomic size difference is in the following increasing order: Ni < CrFeNi < CoCrFeMnNi < Ni-2 at.% W < Ni-4 at.% W. It can be concluded that lattice distortion effect is significant in the dislocation behavior and mechanical properties for 3A and 5A due to the whole-solute lattice distortion.

Generally, high strength is achieved by hindering dislocation motion in crystalline solids; however it often decreases ductility in metal alloys. Therefore, metallurgists have long thought about how to overcome this tradeoff in between strength and ductility. In 2021, a mechanism of HEA was unveiled, in which both the strength and toughness of an alloy could be enhanced through high slip-plane density (Yeh, 2021). In fact, recent studies also support this theory (Stoudt et al., 2000; Yang et al., 2018; Pan et al., 2021). Edge dislocations could induce slip and cause deformation, but they could also pile up at grain boundaries and interfaces to induce crack. Fig. 5 shows the schematic diagram of reduced crack-forming tendency due to the increased density of activated slip plane (Yeh, 2021). The discrete slip bands (a group of activated slip planes) would cause a higher stress concentration against obstacles to initiate cracks than a more uniform slip planes under the same shear strain. Therefore, a concept of high accommodation strategy was proposed to increase the active slip planes and dislocation density, and this could increase both the strength and ductility during deformation. The article (Yeh, 2021) also mentioned that low SFE in a severely distorted lattice in HEAs could inherently enhance the density of active slip planes and can improve both strength and ductility. In addition, small grain size, dislocation cell structure, nanoprecipitates, dense stacking faults, and nanotwins could enhance the accommodation of higher densities of slip planes.

Heat conduction in metals could be affected by solutes and defects (Jain et al., 1969; Venkatasubramanian, 2000). Therefore, lattice distortion effect could also affect the thermal conductivity. The thermal conductivity $k(T)$ of a material at temperature T could

Fig. 4 Schematics of the dislocation configurations in pure metal (below), dilute solution (middle), and concentrated solution (top).

Fig. 5 Schematic diagram of the reduced crack-forming tendency due to increased density of activated slip plane, and the high accommodation capacity strategy to increase the number of activated slip plane and thus increase the strength and ductility.

generally be described according to the relationships in Eqs. (8), (9) (Jain et al., 1969). Cheng et al. (2017) measured the thermal conductivities of as-homogenized Ni—Co—Fe—Cr—Mn alloy series and showed a drop of k with an increase in the number of elements due to more severe lattice distortion in the temperature range of 25 °C to 400 °C.

$$k(T) = \alpha(T) * \rho(T) * C_P(T) \quad (8)$$

$$C_p = \sum X_i C_p^i \quad (9)$$

where $\alpha(T)$ is thermal diffusivity, $\rho(T)$ is density, $C_p(T)$ is specific heat, and X_i and C_p^i are the molar fraction and specific heat of constituent element i , respectively.

Cocktail effect

The term “multimetallic cocktails” was first proposed by Professor Ranganathan (Ranganathan, 2003). It is the overall effect of composition, structure, and microstructure. Properties of HEAs are not as simple as those predicted from the rule of mixture, but mutual interactions between unlike atoms, phase formation, and microstructures. Since HEAs contain at least five major elements in the system, the synergistic responses from the constituent elements can be important. The cocktail effects in HEAs have drawn lots of discussions (Pickering and Jones, 2016). The development of Refractory High Entropy Alloys (RHEAs) is the classic example of the use of cocktail effect. The concept of RHEAs was first reported by the US Air Force Research Laboratory. Senkov et al. (2011a, b, 2010) used the high melting point elements to design RHEAs in order to replace the Co-based and Ni-based alloys; the cocktails of different refractory elements have rendered new high-temperature alloys with not only high melting temperatures but also excellent mechanical properties. They also compared the temperature dependence of the yield strength of Nb₂₅Mo₂₅Ta₂₅W₂₅ and V₂₀Nb₂₀Mo₂₀Ta₂₀W₂₀ RHEAs and two superalloys, Inconel 718 and Haynes 230 (Senkov et al., 2011a). The data of these two RHEAs obvious show that RHEAs possess greater temperature capability than those of conventional superalloys.

Liu et al. (2021) also highlighted the cocktail effect by adding appropriate Cu content, which could increase the aspect ratio of the particular phase in FeCoNiCr_{0.4}Cu_x, resulting in enhanced megahertz electromagnetic wave absorption of magnetic properties. Moreover, the addition of Cr element has been reported to result excellent mechanical properties and corrosion resistance in other HEAs system (Lee et al., 2008; Zhang et al., 2019; Duan et al., 2020). To sum up, by utilizing the cocktail effect, that is, adding suitable elements in HEAs, better combinations of properties for engineering applications can be obtained, providing additional flexibility to HEAs properties design.

Development of special high-entropy alloys

Based on the concept of HEAs, several types of new alloy systems have been developed with promising properties for engineering applications. This section reviews the current state of the art of various special HEAs.

Low-stacking-fault-energy high-entropy alloys (LSF-HEAs)

CoCrFeMnNi and related FCC-type HEAs have been found to possess relatively low stacking fault energies, which generally attribute to both high strength and good ductility. Zaddach et al. (Youssef et al., 2015) reported that for CoCrFeMnNi, both its tensile strength and ductility can be increased at cryogenic temperatures, as deformation-induced twinning becomes a more prominent deformation mechanism (Zaddach et al., 2013). Generally, in low-SFE alloys, dissociation of partial dislocations with a wide spacing is more energetically favorable for the dislocations, cross-slip and climb. So, alloys are more likely to deform by twinning. The low-SFE increases the dislocation storage capacity, increases strain-hardening through the “dynamic Hall–Petch” effect of the deformation twins, and results in an increase of both strength and ductility (Jian et al., 2013). Sarma et al. (2010) described the change in deformation mechanisms in Cu–Al alloys as a function of temperature and SFE. As the Al content increases, the SFE decreases, making twinning as the predominant deformation mechanism. Zaddach et al. (2015) also reported Ni_{18.5}Fe_{18.5}Cr_{18.5}Co₂₆Mn_{18.5}, which contains cobalt to further reduce the SFE, had a 30% improvement in elongation comparing to the equiatomic alloy. Sathiaraj et al. (2020) reported that the mechanical twinning and shear banding at intermediate and high rolling reductions, respectively, are related to the formation of the brass-type rolling texture in the low SFE HEAs investigated.

High-entropy superalloys (HESAs)

Superalloys are important materials for gas turbine engines in aerospace and energy industries (Reed, 2006). Traditional superalloys have relied on ordered Ni₃(Al,Ti)-based L₁₂-structured (γ') coherent precipitates to strengthen the FCC-structured (γ) matrix. During the development of advanced superalloys, Ru and Re elements are of interest due to their contributions to phase stability and creep resistance. In fact, the addition of these two elements in the Ni-based system can be seen as a “quasi-cocktail effect” (Yeh et al., 2004b, 2008; Yeh and Tin, 2005, 2006; Kawagishi et al., 2012). Although creep properties of Ni-based alloys can be improved by adding Ru and Re, high density and high cost prohibit a large scale of applications. Furthermore, the homologous temperature of superalloys has appeared to reach the limit, and efforts on superalloy development have focused on improving the cost performance by reducing the use of expensive elements. However, the Ni-based system actually constrains the composition design space to further reduce the cost and density. Therefore, the concept of HEAs, that is, $\Delta S_{conf} \geq 1.5R$, can open the window to exploit the vast composition space for superalloys development (Yeh et al., 2004a; Gao et al., 2016). The name of High Entropy Superalloys (HESAs) has been given to this class of materials. One of the first HESAs is Al_xCo_{1.5}CrFeNi_{1.5}Ti_(0.5-x) with an FCC γ matrix and uniform dispersion of L₁₂ γ' particles; this alloy can possess higher temperature capability than that of Inconel 718 (Yeh et al., 2014). Chen et al. (2020a) reported the new cast-type HESA system, low-cost element Fe was used to lower down the cost of

material, and lightweight elements such as Al, Ti, and Cr could lower down the density. In addition, alloy design based on elemental partitioning characteristics could control not only the lattice parameters, but also the intrinsic properties of γ matrix and γ' precipitate. The substitution of 2.0 at% Ni by 2.0 at% Ti affected the partitioning characteristics for other elements, resulting in an increase in the entropy of γ matrix, and a decrease in the entropy for γ' phase, which in turn could enhance its thermal stability. Moreover, for oxidation and corrosion resistances of HESAs, the design concept also promoted the formation of protective Al_2O_3 or Cr_2O_3 layers. HESAs have shown superior cost-specific tensile yield strength than that of conventional superalloys. [Chen et al. \(2020b\)](#) also recently reported an interesting hierarchical microstructure strengthening mechanism in a single crystal high entropy superalloy— $\text{Ni}_{48.3}\text{Co}_{16.9}\text{Al}_{10.2}\text{Fe}_{8.9}\text{Cr}_{7.4}\text{Ti}_{5.8}\text{Nb}_{1.2}\text{Mo}_{0.9}\text{W}_{0.4}$ HESA. In addition to the FCC matrix and the L_{12} -structured phase, there were high entropy FCC nanoparticles dispersion within the L_{12} phase. This hierarchical microstructure was achieved through a phase transformation pathway through metastability. Because of the hierarchical structure, HESAs have shown outstanding high-temperature mechanical properties; these materials are promising new alloys with better cost performance than conventional superalloys.

Refractory high-entropy alloys (RHEAs)

RHEAs were originated from the Air Force Research Laboratory (AFRL). [Senkov et al. \(2010, 2011b\)](#) proposed the MoNbTaW and MoNbTaVW RHEAs with a simple BCC solid solution phase. These two kinds of RHEAs possess high hardness and high temperature strength. To further improve the ductility, niobium and tantalum were retained; hafnium, titanium, and zirconium were added; and the result was HfNbTaTiZr RHEA, which is also a stable BCC solid solution. This RHEA possesses a superior room temperature strength and can retain the high hardness as well as the high temperature strength ([Senkov et al., 2011b, 2012](#)). [Senkov et al. \(Senkov and Woodward, 2011; Senkov et al., 2013a,b\)](#) developed $\text{CrMo}_{0.5}\text{NbTa}_{0.5}\text{TiZr}$ and CrNbTiVZr by adding the low-density elements Cr and V instead of the high-density elements Hf and Ta in order to retain the strength and reduce the density. The microstructure of $\text{CrMo}_{0.5}\text{NbTa}_{0.5}\text{TiZr}$ showed Zr-rich Laves phase; however, it can still possess high strength at 800 °C. The other RHEA, CrNbTiVZr , also possessed the same microstructure and property correlation, and the addition of V element could enhance the high temperature strength. The partial substitution of Al element with Cr element in RHEAs system could avoid the formation of laves phases and maintain the oxidation resistance with lower density. Al element could also enhance the strength of BCC SS by strong bonding with transition elements. $\text{AlMo}_{0.5}\text{NbTa}_{0.5}\text{TiZr}$ and $\text{Al}_{0.4}\text{Hf}_{0.6}\text{NbTaTiZr}$ were reported to possess twice the strength of HfNbTaTiZr at room temperature ([Senkov et al., 2014, 2016](#)). [Stepanov et al. \(Stepanov et al., 2015; Yurchenko et al., 2017\)](#) reported the light-weight RHEAs systems, including $\text{AlCr}_x\text{NbTiV}$, $\text{Al}_x\text{NbTiVZr}$, and AlNbTiVZr_x . By adding a number of low-density elements such as Al, Cr, and Ti in the high entropy quantity, the density of RHEAs could be reduced significantly. These kinds of RHEAs possess high strength at room temperature and the microstructure often contains B2 precipitate or laves phase. Alloy design needs to consider the phase formations in RHEAs carefully since Al addition could easily lead to a decrease in melting point and soften the material at high temperatures. RHEAs possessing a low neutron absorption cross-section and a low decay cycle are potential candidates for application in nuclear industry. In summary, RHEAs can be applied to high-temperature applications beyond the temperature capability of nickel-based superalloys.

High-entropy metallic glasses (HEMGs)

The metallic glasses are regarded as promising materials due to high hardness, strength, and elasticity. However, the tensile brittleness after elastic deformation limits the use of metallic glasses as structural materials. Studies have reported that the HEAs can be fully amorphous without crystalline phases after solidification ([Takeuchi et al., 2014](#)). Interestingly, HEMGs could combine the features of both metallic glasses and high-entropy alloys, and may provide a new direction to develop materials with high strength and high ductility. [Gong et al. \(Gong et al., 2020\)](#) demonstrated that TiZrHfBeCu can possess excellent compressive plasticity. [Li et al. \(2019\)](#) reported that the $(\text{Fe}_{1/3}\text{Co}_{1/3}\text{Ni}_{1/3})_{80}(\text{P}_{1/2}\text{B}_{1/2})_{20}$ HEMGs have superior magneto-caloric property in a wide temperature range comparing with those of conventional crystalline materials. [Chen et al. \(2021\)](#) reported that the magnetic properties of HEMGs can be superior to conventional materials and might be promising candidates for the magnetic refrigeration application.

Eutectic high-entropy alloys (EHEAs)

Eutectic alloys are known to possess good castability and excellent mechanical strength ([Otarawanna and Dahle, 2011](#)). Since the eutectic reaction is associated with isothermal transformation, both chemical segregation and shrinkage cavity can be alleviated. Eutectic HEAs (EHEAs) with the composite FCC/BCC structures can possess the advantages of good mechanical properties and excellent castability. [Lu et al. \(2017\)](#) demonstrated the excellent corrosion resistance and strength of $\text{AlCoCrFeNi}_{2.1}$ comparing to those of commercial $\text{CuZn}_{25}\text{Al}_5$ copper alloys used in marine applications. [Jiang et al. \(2019\)](#) developed the $\text{CoCrFeNiNb}_{0.45}$ EHEA with an ultrafine lamellar microstructure; this as-cast alloy also showed outstanding thermal stability and hardness up to 1100 °C. Furthermore, [Ding et al. \(2017\)](#) reported that $\text{AlCoCrFeNi}_{2.1}$ EHEA possessed excellent mechanical properties and good corrosion resistance properties. There is limited studies on the solidification of EHEAs with complete eutectic microstructure; this could be due to the complicated solidification mechanism associated with HEA effects. The underlying mechanism of the solidification behaviors of EHEAs still needs to be further clarified in the future.

High-entropy intermetallic compounds (HEICs)

High-entropy intermetallic compounds (HEICs) are a new class of high-entropy materials, which may fill the knowledge gap between the metallic HEAs and intermetallic HEA compounds. These new HEICs are mostly metallic but also have crystal structures resembling the ionic solid. Zhou et al. (2019) fabricated the HEICs $(\text{Fe}_{0.2}\text{Co}_{0.2}\text{Ni}_{0.2}\text{Mn}_{0.2}\text{Cu}_{0.2})\text{Al}_1$ with a B2 structure and $(\text{Ti}_{0.25}\text{Nb}_{0.25}\text{V}_{0.25}\text{Zr}_{0.25})\text{Al}_3$ with a D0₂₂ structure. Yao et al. (2021) developed the HEICs $(\text{Fe}_{0.75}\text{Co}_{0.75}\text{Ni}_{0.75}\text{Cu}_{0.75}\text{TiZrHf})$ with B2 ordering and showed an ultrahigh compressive yield strength of 2.25 GPa and a fracture strength of 2.52 GPa. Moreover, this HEICs possessed high thermal stability. The atomic-size dispersity δ , which is shown in Eq. (7), is one of the phase selection criteria. Furthermore, this work adapted previous concept (Gargarella et al., 2011) and proposed a new criteria to better describe how the electronegativity of the central atom could be affected by the neighboring atoms; a probability coefficient of direct electronegativity difference, μ , is then considered as shown in Eqs. (10), (11). Therefore, the atomic-size dispersity, δ , and the overall electronegativity difference, η , could be employed to reveal that HEICs are prone to form in the region of $\delta \geq 5.5$ and $0.2 \leq \eta \leq 0.4$.

$$\eta = \sqrt{\sum_{i=1}^n c_i \left[\sum_0^\mu (e_i - e_j) \right]} \quad (10)$$

$$\mu = c_j V m_j^{2/3} / \sum_0^{c_j} V m_j^{2/3} \quad (11)$$

where $e_i - e_j$ is the direct Pauling's electronegativity difference between central and neighbor atoms, μ is the probability coefficient, c_i and c_j are the atomic fractions for the corresponding element, and $V m$ is the molar volume.

High-entropy coatings (HE-Coatings)

The HE-Coatings can compose of HEAs and HEA-based materials, including metal, ceramics, and composites. Not only the materials of HE-Coatings are diverse, but also are the fabrication processes. The first two papers on HEA-based coatings were published by Prof. Jien-Wei Yeh's team (Huang et al., 2004; Chen et al., 2004); these included HEA nitride films with more than five elements fabricated by magnetron sputtering, and AlSiTiCrFeCoNiMo_{0.5} and AlSiTiCrFeNiMo_{0.5} coatings fabricated by thermal-spray technique. HEA-based coatings have the potential to be applied as diffusion barrier and high-temperature protective coating. Chang et al. (2014) reported the suppressed interdiffusion kinetics in high-entropy coating film and it could be a diffusion barrier to improve the Cu/TaN interface in the IC technology. Hsu et al. (2018, 2016) studied the NiCo_{0.6}Fe_{0.2}Cr_xSiAlTi_y system as high-temperature protective coating. The results indicated that HE-Coatings could possess high hardness and excellent wear resistance due to the formation of Nb—Si compounds at the interface. In addition, the thermal conductivity of NiCo_{0.6}Fe_{0.2}Cr_{1.5}SiAlTi_{0.2} was lower than commercial MCrAlY by 30% at elevated temperature and exhibited smaller thermal expansion than that of MCrAlY for better compatibility with the substrate turbine blade alloys.

Future perspective

There are still many challenges ahead to study and develop future HEA-based materials. For example, the cocktail effect allows more flexible alloy design to improve properties of HEAs; however, due to the complexity of HEAs systems, mechanisms of different cocktail effects can interact with each other and become very complex. There are ongoing efforts to develop CALPHAD-based tools to predict phases in HEAs, but lots of research works are still needed in order to improve the prediction capability and accuracy; artificial intelligence or machine learning may assist the effort to speed up the development of a prediction tool for the cocktail effects of HEAs in the future. Sluggish diffusion and lattice distortion have been proven in HEAs; however, how to employ these concepts in the actual alloy design has remained a challenge, and this clearly needs an accurate phase prediction tool for HEAs. Furthermore, research works on the deformation behaviors of HEAs have been conducted on polycrystalline samples, in order to study the effects of intrinsic HEA compositions, the fabrication of single crystal samples is of interest, especially for RHEAs. Nevertheless, "High-Entropy Alloys" have become one of the most important material research fields. The concept of HEAs has given the community a novel idea of material design, to develop new structural and functional materials for various applications. Nowadays, the research activities of HEAs are growing rapidly; we believe that in the near future, the concept of HEAs can have many positive impacts to our society and make the world more wonderful.

Conclusion

There are still many challenges ahead to study and develop future HEA-based materials. Due to the complexity of HEAs systems, mechanisms of different cocktail effects can interact with each other and become very complex; this should be a subject of interest for future study. There are ongoing efforts to develop CALPHAD-based tools to predict phases in HEAs, but lots of research works are still needed to improve the prediction capability and accuracy; artificial intelligence or machine learning may assist in the effort to speed up the development of a prediction tool for the cocktail effects of HEAs in the future. Sluggish diffusion and lattice distortion have been proven in HEAs; however, how to employ these concepts in the actual alloy design has remained a challenge.

Furthermore, research works on the deformation behaviors of HEAs have been conducted on polycrystalline samples, to study the effects of intrinsic HEA compositions, the fabrication of single crystal samples is of interest, especially for RHEAs. Nevertheless, “High-Entropy Alloys” have become one of the most important material research fields. The concept of HEAs has given the community a novel idea to develop new structural and functional materials for various applications. Nowadays, the research activities of HEAs are growing rapidly; we believe that in the near future, the concept of HEAs can have many positive impacts to our society and make the world more wonderful.

Abstract

Metal halide perovskites have been widely investigated for their potential to replace standard semiconductors in a range of applications including solar cells and light-emitting diodes because high-quality materials with high charge-carrier mobilities and long charge-carrier lifetimes can be relatively easily synthesized in a variety of morphologies using many different techniques. Furthermore, their optoelectronic properties including bandgap energy can be altered with simple chemical substitution, allowing for materials to be tuned for specific applications. Despite issues with stability and toxicity, some highly efficient devices have been fabricated, and the number of potential applications continues to grow.

Key points

- In recent years halide perovskites have attracted much attention due to their potential application in many optoelectronic devices, including photovoltaic cells.
- Their promise in a range of applications stems from their ease of synthesis and their unique set of optoelectronic and physical properties, including strong optical absorption and long charge-carrier diffusion lengths.
- The tunability of halide perovskite properties with chemical composition and morphology has resulted in the development of different types of materials and synthetic methods.
- However, two main obstacles, stability and toxicity, are currently hindering the realization of commercialization of perovskite-based devices, although a large research effort has been dedicated to address these issues.

Introduction

In the last decade, research on metal halide perovskites (MHPs) has increased dramatically due to their promising applications in photovoltaic (PV) cells and other devices. This meteoric rise has been enabled both by the superior optical and electronic properties of these materials and by their ease of synthesis, making them attractive alternatives to standard inorganic semiconductors for applications ranging from light-emitting diodes to nonvolatile memory devices (Jena et al., 2019). They are also intriguing due to their usual combination of physical properties, which includes high charge-carrier mobilities, low thermal conductivity, and defect tolerance among others. Due to all of this interest, thousands of publications about halide perovskites are added to the literature every year, and products are approaching commercialization, including silicon-perovskite tandem solar cells.

This article provides a brief overview of what has made MHPs so interesting to many researchers, focusing on how their unique set of physical and chemical properties has enabled the development of devices. It is by no means an exhaustive review of the subject, and the reader is referred to the many more specific review articles cited in this overview.

Overview

Brief history of the field

The discovery of perovskites in general can be traced back to 1839, when mineralogist Gustav Rose identified the naturally-occurring, oxide perovskite CaTiO_3 , naming it in honor of nobleman and amateur mineralogist Lev Perovski (Jena et al., 2019). The synthesis of CaTiO_3 in 1851 led to the development of other oxide perovskites including BaTiO_3 and LiNbO_3 , which have been evaluated since then for their ferroelectric, piezoelectric, dielectric properties, among others. Alongside these investigations for oxide perovskites, inorganic metal halide perovskites including CsPbX_3 ($X = \text{Cl}^-$, Br^- , or I^-) were first synthesized in the 1890s, with analogous materials incorporating organic species (for example $\text{CH}_3\text{NH}_3\text{PbX}_3$, $X = \text{I}^-$, Br^-) first reported about 80 years later in the 1970s. From this point, however, the tunable nature of the chemical structure was exploited by a couple of pioneering groups, who reported a greatly expanded range of materials with different organic and metal cation species. The potential application in light-emission, nonlinear optics, and thin-film transistors was also identified at this time (Kagan et al., 1999; Jena et al., 2019). While applications in PV were purportedly also discussed at this time, they were discounted due to concerns over lead toxicity, coupled with the tendency for tin-containing MHPs to degrade (Green et al., 2014).

The explosion of interest in MHPs that has shaped the field today did not come until after the first demonstration of a solar cell containing an MHP in 2009, however (Kojima et al., 2009). This solar cell was based on the working principles of a dye-sensitized solar cell (DSSC), where an MHP acted as the sensitizing layer on a metal-oxide surface. At the time, the DSSC field was well established, with many researchers focused on the topic world-wide, but the maximum reported efficiencies of cells had remained around 10% for about a decade (NREL, 2021). Although the first report of an MHP cell gave efficiencies of only 3.8% (Kojima et al., 2009), this value was improved to 10.9% by Lee et al. (2012), which rivaled the best performing DSSCs. Furthermore, concurrent studies of the fundamental properties of metal halide perovskites found that they have high charge-carrier mobilities, long charge-carrier lifetimes, and therefore long charge-carrier diffusion lengths, which suggested that perovskite solar cells could achieve much higher efficiencies (Johnston and Herz, 2016). Combined with their ease of synthesis, this success enabled the popularity of perovskites to grow rapidly. Over the next decade, solar cell efficiencies would exceed 25%, rivaling silicon technologies and approaching the fundamental limit for the efficiency of a single junction solar cell (NREL, 2021). Following this success, perovskites have also been investigated for a range of other optoelectronic applications including photodetection (Wang and Kim, 2017), photocatalysis (Ren et al., 2022), and light-emission (Otero-Martinez et al., 2022), and there are now several businesses looking to commercialize perovskite technologies.

Structure of MHPs and related materials

MHPs adopt the classic ABX_3 structure, where A is a monovalent cation, B is a divalent metal cation, and X is a halide anion (Fig. 1). This perovskite structure can be visualized as a set of corner-sharing BX_6 octahedra in which the A-site cation occupies the cuboctahedral cavities created by the three-dimensional network of octahedra.

Fig. 1 The Goldschmidt Tolerance Factor and its influence on the structure of hybrid perovskites. (left) Illustration of the perovskite structure and a visualization of the geometric arguments that give rise to the Goldschmidt tolerance factor. (right) Cartoons illustrating the effects of non-ideal Goldschmidt tolerance factors on perovskite crystal structures.

Many different compositions of MHPs have been reported, and this tunability of structure is what makes these materials attractive for many different applications because the optoelectronic properties also tune with chemical composition. Commonly, a small organic alkylammonium cation such as methylammonium (MA, CH_3NH_3^+) or formamidinium (FA, $\text{CH}(\text{NH}_2)_2^+$) is used as the A-site cation. As this cation is not bonded to the metal covalently and therefore does not form an organo-metallic compound, metal hybrid perovskites are often given the additional classification as hybrid due to their mixed organic-inorganic components. However, all-inorganic varieties such as CsPbI_3 are included in the more general MHP classification. For both hybrid or all-inorganic varieties, the metal cation is typically lead (II) or tin (II), but a range of other divalent metal cations has been reported including germanium, copper, cobalt, palladium, and many more (Wang et al., 2019). Many other possible compositions have been also identified computationally (Filip and Giustino, 2018). Of the halides anions, iodide and bromide are most commonly used, but chlorine-based MHPs have also been synthesized. Pseudo-halides such as cyanide (CN^-) or thiocyanate (SCN^-) have also been reported and are sometimes discussed in the same context as MHPs.

With such a variety of options, it is important to discuss what the limits are to perovskite formation. The Goldschmidt tolerance factor (GTF) is often used to predict the formation of MHPs based solely on the sizes of their constituent ions. First proposed for metal oxide perovskites in 1926, the tolerance factor is defined as follows, where the subscripts A, B, and X correspond to the organic cation, metal cation, and halide, respectively, and r is the ionic radius.

$$t = \frac{r_A + r_X}{\sqrt{2}(r_B + r_X)}$$

The tolerance factor constitutes what is commonly referred to as the “no-rattling” principle of structural design which seeks to maximize the number of anions around a cation while ensuring that all the anions touch a cation (Filip and Giustino, 2018) and can be obtained from a simple geometric argument, which is outlined in Fig. 1. This argument can be understood by considering two ‘slices’ through the perovskite unit cell: one through a plane containing the metal and halide ions and another containing the divalent cation and halides (highlighted as red and blue in Fig. 1, respectively).

For a cubic perovskite, we expect the ‘size’ of these slices to be equal and for halide and metal ions to stack perfectly on top of each other. For this to be true, the distances from the atoms at the corners of the crystal to the center of each slice (given by the black arrows in the red and blue boxes) must also be equal. We can express this distance in terms of the ionic radii of the constituent ions in two different ways, as shown in Fig. 1. The tolerance factor is simply a ratio of these two lengths. If the two lengths are equal, then $t = 1$.

A tolerance factor of 1 thus indicates a perfect cubic structure as shown in Fig. 1, but cubic structures are possible for MHPs with values as low as about 0.9 (Wang et al., 2019). For example, FAPbI_3 has a tolerance factor of 0.89 at room temperature but still adopts a cubic crystal structure. For values of 0.7–0.89, structures which maintain the perovskite coordination are still possible, but are distorted from the cubic structure because of the poor ‘fit’ of the ions. For example, substituting the formamidinium cation with the smaller methylammonium decreases the tolerance factor to 0.84 and results in a tetragonal crystal structure at room temperature in which the Pb—I octahedra are tilted with respect to the ideal cubic structure, and the lattice constant is larger in one dimension than in the other two (Fig. 1).

Values of t greater than 1, where perovskite structures generally do not form, are most often obtained when the A-site cation is too large. However, stable perovskite-like structures are possible including 2D or layered perovskites, in which a layer or layers of metal-halide octahedra are separated by a layer of larger organic cations as shown in Fig. 1 (Sirbu et al., 2021).

The flexibility in the tolerance factor means that mixed or alloyed structures are also possible, increasing the synthetic space and tunability even more. One example is the so-called double perovskites in which the B-site divalent cation is replaced with a monovalent cation and trivalent cation in equal proportion, i.e., CsInAgCl_6 or $\text{Cu}_2\text{AgBiI}_6$. Non-stoichiometric mixtures, in which one or more of the components is mixed with an ion of the same valence in an arbitrary proportion, are also possible. Some common examples include mixed halides such as $\text{FAPb}(\text{Br}_y\text{I}_{1-y})_3$, where y can have any value between 0 and 1, mixed-cation compositions such as $\text{FA}_x\text{Cs}_{1-x}\text{PbI}_3$, and mixed lead-tin materials. It is also possible to mix two or more of the components as in $\text{FA}_{0.75}\text{Cs}_{0.25}\text{Sn}_{0.5}\text{Pb}_{0.5}\text{I}_3$ or $\text{FA}_{0.83}\text{Cs}_{0.17}\text{Pb}(\text{I}_{0.5}\text{Br}_{0.5})_3$. Through careful selection of the ionic radii of the perovskite’s constituents, the optical and structural properties of the material can be controlled, giving researchers a powerful tool to tune the desirable characteristics of the material, as will be discussed in more detail in later sections.

Although the Goldschmidt Tolerance Factor has been shown to predict 80% of possible perovskites (Filip and Giustino, 2018), it is not a perfect predictor of crystal structure in hybrid perovskites for several reasons:

- 1) The traditional implementation for GTFs assumes spherically symmetric A-site species. The organic cations in hybrid perovskites are clearly non-spherical, which makes assigning an ionic radius challenging.
- 2) The geometric arguments that give rise to the tolerance factor assume hard spheres for the ionic species. This assumption breaks down for the B-site species Pb and Sn, as well as for heavier halide ions, such as bromine and iodine.
- 3) Tolerance factors primarily apply to thermodynamic minima, however given the low temperatures at which hybrid perovskites are commonly synthesized, kinetic trapping of otherwise non-ideal states is possible.

As a result, there have been several attempts to modify the Goldschmidt tolerance factor to better apply to hybrid perovskites, for example through the use of data-mining and machine learning approaches (Filip and Giustino, 2018; Kieslich et al., 2015; Sato et al., 2016; Travis et al., 2016), by revising values for the ionic radii of the halide and organic cation species to account for bond covalency (Travis et al., 2016) or else by applying more sophisticated geometric models beyond the hard-sphere model initially proposed (Travis et al., 2016; Kieslich et al., 2015).

Synthesis

One of the most appealing properties of MHPs is that high quality materials can be synthesized at ambient temperatures and pressures. This ease of synthesis gives them an advantage over traditional inorganic semiconductors such as silicon whose syntheses typically require high temperatures of over 1000 °C (Jena et al., 2019). Furthermore, MHPs can be synthesized in many different morphologies including polycrystalline thin films, quantum dots, nanowires, nanoplatelets, single crystals, and powders, providing further opportunities to tune materials for device applications (Fig. 2).

Most MHP syntheses involve the combination of a metal halide salt and an organic (or cesium) halide salt in equal molar quantities to create the desired perovskite. For example,

While this basic equation dictates the main chemical composition of the perovskite material, the experimental conditions can further fine-tune the properties and morphology of the MHP that is created. Synthetic methods can roughly be divided into those that involve combining the starting materials in a solvent (for example spin-coating or ink-jet printing) and solvent-free methods (e.g., vapor deposition). Solvent-based methods have been the most popular to date due to their relative ease and the low cost of associated equipment, although solvent-free methods are also popular because of their potential for scalability.

MHPs are most commonly synthesized as polycrystalline thin films with thicknesses a few 100s of nanometers because this is the architecture most useful for devices such as solar cells and LEDs. A further benefit for devices, thin films can be prepared on a range of substrates by various methods including spin-coating, vapor deposition, or ink-jet printing. As a result, much research has been dedicated to optimizing the synthesis of thin films (Dunlap-Shohl et al., 2019).

The most basic and widely used solution-processing technique for metal halide thin films is spin-coating (Dunlap-Shohl et al., 2019). In a one-step procedure, the starting materials are dissolved in a polar, aprotic solvent such as dimethyl sulfoxide (DMSO), dimethylformamide (DMF), γ -butyrolactone (GBL), or mixtures of such solvents. These polar solvents are needed because of the low solubility of lead in other common organic solvents. The solution is then dropped onto a substrate (usually glass or coated glass) spinning at hundreds to thousands of revolutions per minute. Films with uniform thicknesses typically from 100 nm to 500 nm form spontaneously as the solvent evaporates and is driven off the substrate by spinning. While the substrate is spinning, an

Fig. 2 The diversity of synthetic techniques and morphologies of hybrid perovskites, including single crystals (a–c) and thin films (d–f). A wide diversity of hybrid perovskite nanostructures also exist, including hybrid nanostructures (g–i), nanowires (j–l), nanocrystals (m and n), and nanoplatelets (o–q). Subfigures (a–c) adapted from Ma et al. (2021), (e and f) from Jia et al. (2021), (g) from Meng et al. (2016), (h and i) from Mao et al. (2017), (j) from Im et al. (2015), (k and l) from Dou et al. (2017), (m) from Bera et al. (2020), (n) from Protesescu et al. (2015), (o and q) from Weidman et al. (2016), and (p) from Dou et al. (2015).

“antisolvent” such as the non-polar toluene might also be applied to aid crystallization and the formation of uniform films. After spinning, the films are usually annealed at temperatures between 100 °C and 200 °C to drive off any remaining solvent and improve crystallinity and film morphology. In addition this one-step method, two-step methods are also common in which a metal halide film is deposited first and allowed to dry. The organic halide is then incorporated separately either in the solution, vapor, or solid phase. The perovskite film then forms as the organic halide ions diffuse through the metal halide film.

Much work has been done to tune spin-coating methods to optimize thin films for device applications. The ideal thin film for device applications should be highly crystalline, have large grain sizes, be free of pinholes, and have lower impurity or defect densities. Some common methods to achieve these goals include forming the films in an excess of starting material, including various additives into the starting solution, post treating with different solutions or gases, and many more. For a more complete overview of these strategies, see the review article by Dunlap-Shohl et al. (2019).

In addition to spin-coating, other solvent-based deposition techniques have been investigated for thin films, with the aim of making film synthesis more scalable in a manufacturing setting (Dunlap-Shohl et al., 2019). One example is blade-coating, where the solution of starting materials is drawn across the substrate using a blade at fixed height. Similarly, slot-die coating involves passing the starting solution through a narrow die at a fixed rate and then moving the die relative to the substrate in order to produce the desired film. Both blade-coating and slot die coating are important for the development of roll-to-roll processing methods. Another method identified for its commercial promise is spray-coating, where the solution is aerosolized through injection through a nozzle, which is then directed toward a substrate. Ink-jet printing is a variation on this method that enables patternable deposition of thin films.

Thin films can also be prepared by several solvent-free approaches. The more popular solvent-free approach is thermal evaporation (Xiang et al., 2022). In dual-source thermal evaporation, a substrate is placed in a chamber under high vacuum (typically 10^{-5} to 10^{-7} Torr). The solid starting materials are then evaporated in separate crucibles and directed toward the substrate where the vapors combine and form the perovskite film. The evaporation rates of the starting materials are controlled in order to tune the stoichiometry of the vapor. Similarly, chemical vapor deposition (CVD) methods have also been investigated (Raiford et al., 2020). In CVD, an inert flow gas such as nitrogen or argon transports the vaporized starting materials into a vacuum chamber where the components react and deposit on a substrate. As with solution processing, both one-step methods, where the all starting materials are introduced at once, and two-step methods, where the metal halide is deposited first, are possible. CVD chambers can operate at higher pressures than thermal evaporation systems (typically 10^{-3} Torr—i.e., atmospheric pressure).

Additionally, perovskite nanomaterials including quantum dots (Le et al., 2018; Xu et al., 2021), nanoplatelets (Otero-Martinez et al., 2022), nanowires (Zhang et al., 2022; Wang et al., 2022), and more have been synthesized. Nanomaterials can be formed through a variety of processes, many of which resemble synthetic methods for thin films (Le et al., 2018; Xu et al., 2021). As with thin films, the most popular methods for nanoparticle synthesis are solution-based. The difference between nanomaterial and thin film synthesis is that nanomaterials are formed in the presence of organic ligands such as oleic acid or oleylamine which serve to limit the growth of the particles and passivate surface defects (Xu et al., 2021; Le et al., 2018). In the commonly used hot injection method, a solution containing the A-site cation and ligands is prepared at room temperature. A separate solution of the metal halide and ligands is prepared and heated to temperatures from 100 °C to 200 °C and then added to the other solution. Typically, there is also a post processing step to remove some of the ligands to facilitate charge transport and make the particles more suitable for device applications. Some ligands are left, however, to prevent agglomeration and maintain defect passivation. For most solution-based syntheses, the size and shape of the nanomaterials is controlled by a range of factors including the temperature of the reaction, acid-base equilibrium of the ligands, ligand chain length, and ligand concentration.

Nanoparticle size and shape can also be controlled using templates. Although templated growth of perovskite quantum dots has been reported (Le et al., 2018), template methods are more often employed for nanowires (Zhang et al., 2022; Wang et al., 2022). In a blade-coating technique analogous to that for thin films, a solution of starting materials is deposited on a substrate templated with the desired dimensions of nanowires, and a blade is then drawn across the surface of the substrate to remove excess material, leaving the nanowires behind. Additionally, vapor deposition techniques can be used to grow nanowires vertically from a template both with and without a catalyst in an analogous fashion to more standard inorganic semiconductor nanowires. A template can also be applied following the deposition of a thin film, as with nanowires etched using a focused-ion beam (FIB).

In addition to thin films and nanomaterials, synthesis of bulk materials has also been a focus due to their perceived chemical purity. Large single crystals (with lengths ~ 1 cm) can be grown through a variety of solution based methods (Murali et al., 2020). These methods generally involve the saturation of a solution of starting materials, and slow growth of the crystal is controlled by temperature or solvent engineering. As many of the crystals formed through these methods are too thick for device applications, much research is focused on developing methods to control the growth of thinner crystals (Murali et al., 2020). Smaller crystals and powders can be prepared with similar methods but they can also be synthesized using mechanosynthesis, a solvent free technique in which the solid starting materials are mixed and ground together to form the desired perovskite (Kubicki et al., 2021; Rosales et al., 2019). This technique has the advantage that perovskites with clear chemical compositions can be synthesized and insolvent dopants can be incorporated. It is currently most used to create samples for detailed spectroscopic studies but is also being investigated for device applications (Prochowicz et al., 2019).

Physical, optical, and optoelectronic properties

Many of the unique features of hybrid perovskites, for instance the combination of organic and inorganic species within the same lattice, the use of large and polarizable B- and X-site species, as well as the diverse morphologies that can be adopted by these

materials leads to a wide variety of interesting and exotic material properties. Exploring these properties remains a vibrant area of study, and is essential to improving their performances in existing applications (for example, as solar absorbers), as well as motivating and discovering new technological applications and use cases.

Optical properties

Optical absorption and photoluminescence

Most metal halide perovskites are semiconductors with bandgaps in the visible region of the electromagnetic spectrum (Fig. 3), which is one of the main features that makes them attractive for photovoltaic and other optoelectronic applications. Additionally, they normally have high absorption coefficients of $\sim 10^4$ – 10^5 cm⁻¹ and exhibit high luminescence efficiencies. For example, the prototypical MAPbI₃ has a bandgap of 1.61 eV (770 nm) and an absorption coefficient which is 1×10^4 cm⁻¹ at the band edge but which then increases above the bandgap to 3.8×10^4 at 2.0 eV (620 nm) and is even higher in the UV (Shirayama et al., 2016). As a result, the penetration depth for visible light in MAPbI₃ and similar materials is on the order of 1 μm or less.

The optical transitions in perovskites are strong due to the nature of the molecular orbitals which make up the conduction and valance bands. Density functional theory (DFT) calculations for lead-based MHPs suggest that the valance band maximum is

Fig. 3 Optical properties of hybrid perovskites. (a) Simplified band diagram of a perovskite, highlighting both the excitonic and continuum bands that give rise to distinct absorption features; (b) Schematic of a typical absorption spectrum of a halide perovskite highlighting the contributions from excitonic (blue dashed line) and continuum (orange dashed line) states—the photoluminescence spectrum is red-shifted relative to the absorption edge. (c–g) tuneability of the optical properties of halide perovskites: (c–e) absorption, PL spectra, and images of Subfigures (c–e) adapted from Zheng W, Huang P, Gong ZL, Tu D, Xu J, Zou QL, Li RF, You WW, Bunzli JCG and Chen XY (2018) Near-infrared-triggered photon upconversion tuning in all-inorganic cesium lead halide perovskite quantum dots. *Nature Communications* 9; subfigures (f) and (g) adapted from Jacobsson TJ, Correa-Baen JP, Pazoki M, Saliba M, Schenk K, Gratzel M and Hagfeldt A (2016) Exploration of the compositional space for mixed lead halogen perovskites for high efficiency solar cells. *Energy & Environmental Science* 9: 1706–1724.

formed by 6s orbitals of lead and 5p orbitals of iodide, and the conduction band minimum is made up of primarily the 6p orbitals of lead (Jena et al., 2019), and significant spin orbit coupling from the heavy atoms used in MHPs makes the bandgaps lower than they otherwise would be (Herz, 2016). Furthermore, the optical transition from the valence band to the conduction band involves the *p*-orbitals associated with both the halide and metal. As these orbitals create a higher density of states near the band edge than *s*-orbitals, perovskites have higher absorption coefficients as compared to semiconductors like GaAs whose conduction band is composed of *s*-orbitals (Manser et al., 2016).

Excitons also play a key role in the absorption properties of MHPs, even though the exciton binding energies of most 3D perovskites are on the order of 10–20 meV or less (Baranowski and Plochocka, 2020) and excitonic species are not present in large concentrations at ambient temperatures where $kT \sim 25$ meV. Fig. 3a and b highlights the position of the excitonic states relative to the valence and conduction bands of a typical hybrid perovskite. In general, so-called Wannier-Mott excitons are expected to be the dominant excitonic species within MHPs, and thus the energy levels of the excitons can be straightforwardly related to the bandgap of the material as follows

$$E_n = E_g - \frac{R_0 \mu}{m_0 \epsilon_r^2 n^2},$$

where R_0 is the Rydberg constant, m_0 is the mass of an electron, ϵ_r is the dielectric constant, and μ is the reduced mass of the exciton ($1/\mu = 1/m_h + 1/m_e$, where m_e and m_h are the effective electron/hole masses). Combining this relationship with a suitable model for the band-to-band transitions of the material allows for the prediction of their band-edge absorption properties. For 3D hybrid perovskites, this is described by the Elliot Formula (Elliott, 1957; Baranowski and Plochocka, 2020), which takes the form

$$\alpha(\hbar\omega) = A \cdot \left(\Theta(\hbar\omega - E_g) \cdot D_{cv}(\hbar\omega) \cdot \frac{\pi x \cdot e^{\pi x}}{\sinh \pi x} \right) + \frac{A \cdot R_0 \mu}{m_0 \epsilon_r^2} \sum_{n=1}^{\infty} \frac{4\pi}{n^3} \cdot \delta(\hbar\omega - E_n),$$

where A is a proportionality constant related to the transition matrix element, $\hbar\omega$ is the photon energy, Θ is the Heaviside (or step) function, δ is the Dirac delta function, D_{cv} is the joint density of states, and x is a parameter related to the photon energy by:

$$x = \sqrt{\frac{R_0 \mu}{m_0 \epsilon_r^2} (\hbar\omega - E_g)}$$

A sketch showing the contribution of the excitonic progression and continuum to the overall absorption spectrum is given in Fig. 3b, where the excitonic and continuum contributions are given in blue and orange, respectively. It is important to note that the impulsive behavior of the Heaviside and delta functions only truly describe the absorption of the perovskite in the absence of instrument or other broadening effects; consequently, it is usually necessary to convolute the model with a suitable lineshape function. It is also important to note is that the Elliot Formula typically only accurately models the band-edge absorption of the perovskite within a few hundred meV of the absorption edge. This limit arises from several assumptions of the model, specifically that (i) only a single band-to-band transition is involved in the continuum, (ii) the transition matrix element (contained within the proportionality constant, A) is constant for all photon energies, and (iii) that the relevant bands are parabolic and isotropic (Davies et al., 2018). Nevertheless, fitting of absorption data with the Elliot Formula provides a (relatively) straightforward means of relating the optical properties of hybrid perovskites to their electronic dynamics. For a more detailed description of these processes, along with alternative methods of relating optical and excitonic dynamics of the perovskite, the reader is advised to consult (Baranowski and Plochocka, 2020) and (Davies et al., 2018).

As with many of the other properties discussed elsewhere in this chapter, alteration of the composition of the perovskite changes their absorption and emission properties. This is clearly demonstrated in Fig. 3c, d, f which highlights how alteration of the halide content of the perovskite results in a dramatic alteration of both the absorption onsets and the emission maxima (Jacobsson et al., 2016; Zheng et al., 2018). As the halide composition is changed from I to Br to Cl, the bandgap shifts continuously over a range of several hundred nanometers when mixed halide compositions are included. In general, decreasing the atomic radius of the halide (e.g., Br – I) increases the bandgap energy due to the contribution of the halide to the density of states (DOS) of the valence band maximum (Wang et al., 2019).

For similar reasons as the halide, the identity of the B-site cation can also have an effect of the bandgap. However, changing the metal ion has a more complex effect on the bandgap energy due to both spin-orbit coupling effects associated with large cations such as lead and structural distortions of the lattice due to size changes of the ions (Herz, 2016). In MAPbI₃ for example, substituting lead for tin decreases the bandgap to 1.25 eV (990 nm) whereas switching to germanium increases the bandgap to 1.90 eV (652 nm) (Manser et al., 2016). Furthermore, mixed Pb–Sn perovskites exhibit an unusual bandgap bowing effect, where compositions with about 50–70% tin exhibit the narrowest bandgaps (Parrott et al., 2018).

Changing the cation can also alter the bandgap energy, but to a lesser extent than the halide and B-site cation. For example, FAPbI₃ and MAPbI₃ have band edges of 1.47 eV (843 nm) and (1.55 eV), respectively (Jena et al., 2019). This smaller change is because the A-site cation does not contribute significantly to the valence and conduction bands. However, the identity of the A-site cation can indirectly change the bandgap energy by altering the size and orientation of the network of metal-halide octahedra (Manser et al., 2016).

The presence of impurities or dopants can also alter the bandgap energy of MHPs. As such, reported bandgaps often vary depending on the preparation method or morphology of a MHP with a given composition. For highly doped materials such as p-doped tin perovskites, the Burstein-Moss effect can result in significant shifts in bandgap energy with doping density (Milot et al., 2018).

The excitonic component of the absorption is distinctly more pronounced in some perovskites than in others. In general, the dielectric constant of many perovskites is relatively large, meaning that their exciton binding energies are often quite small, sometimes even below the ambient thermal energy (~ 25 meV), as is the case with MAPbI₃ (~ 12 meV), which in turn suppresses the excitonic contribution to the band-edge absorption. One strategy to enhance the excitonic character of MHP absorption includes encouraging quantum confinement effects through the synthesis of perovskite nanocrystals or nanoplatelets or through compositional engineering. When the size of a particle is on the order of or smaller than the exciton Bohr diameter, the bandgap is blue shifted with decreasing particle size. For example, the bandgap of CsPbCl₃ increases from 2.4 to 2.7 eV as the particle diameter decreases from 12 nm to 3 nm (Protesescu et al., 2015). Another way to alter the excitonic character of perovskites is through compositional engineering. 2D layered perovskites, which experience increased confinement due to the dielectric mismatch between the conducting metal-halide octahedra and insulating organic layers, have exciton binding energies of up 100s of millielectronvolts and correspondingly blue-shifted absorption spectra (Sirbu et al., 2021). Their exciton binding energy and absorption can be further tuned through the mixture of long and short organic cations via the formation of Ruddlesden-Popper phases, in which it is possible to vary the thicknesses of the metal-halide layer between the insulating organic layers (Sirbu et al., 2021; Milot et al., 2016).

Changes in bandgap energy generally correspond to changes in the photoluminescence energy as highlighted in Fig. 3c, d. Typically, observed Stokes shifts are moderate, although highly doped materials exhibit larger shifts (Milot et al., 2018). For more specific information about the PL properties of MHPs, see the review article by Goetz et al. (2020).

Vibrational absorption and structural dynamics

The vibrational absorption properties of perovskites are key to understanding their structural dynamics, which carry important implications for the optoelectronic properties of the material and thus its performance in devices. These structural dynamics can be described in terms of two closely related regimes of motions: oscillations of the A and BX₃ sublattices and rotation of the A-site cations.

An example infrared/THz spectrum of the archetypal MAPbI₃ perovskite is given in Fig. 4. Hybrid perovskites exhibit a rich and complex vibrational structure owing to the interplay between the organic small-molecule A-site ions and the inorganic BX₃ cage. Broadly speaking, we can delineate four regimes of vibrational motion in these materials: (i) internal vibrations and rotations of the

Fig. 4 Vibrational Properties of MAPbI₃. The top figure is a combined infrared and THz spectrum of MAPbI₃ at ~ 5 K, adapted from Perez-Osorio MA, Milot RL, Filip MR, Patel JB, Herz LM, Johnston MB and Giustino F (2015) Vibrational properties of the organic inorganic halide perovskite CH₃NH₃PbI₃ from theory and experiment: Factor group analysis, first-principles calculations, and low-temperature infrared spectra. *Journal of Physical Chemistry C* 119: 25703–25718. The vibrational structure of these materials can be understood as arising from three different regimes of vibrational motion which are visualized in the lower subfigures.

inorganic cage; (ii) rotations and vibrations of the organic cations; (iii) internal vibrational modes of the organic cations; (iv) so-called ‘mixed’ or ‘hybrid’ modes, where translations and rotations of the A-site ions and BX_3 sublattice occur in concert. Cartoons illustrating representative examples of these modes are given in Fig. 4; more detailed discussion and assignment of the vibrational structure of MAPbX_3 can be found in Perez-Osorio et al. (2015) and Leguy et al. (2016), while discussion of the vibrational structure of FA-containing perovskites can be found in Ibaceta-Jaña et al. (2020) and Kucharska et al. (2014). The complexity of this rich vibrational structure is further compounded by the relatively ‘soft’ nature of most hybrid perovskites—a term that describes both their mechanical properties (i.e., low bulk moduli), as well as the relative freedom of the ionic species to move around their equilibrium positions—which results in highly anharmonic and multi-well modes that are strongly populated at room temperature (Egger et al., 2018). This anharmonicity enables coupling between many different types of nuclear motion, leading to multi-mode vibrational bands in which the motions of both the organic and inorganic sublattices contribute to the overall mode. The behavior is most pronounced for the ‘hybrid’ modes mentioned previously, but theoretical calculations indicate that it is nevertheless present at some level for virtually all of the low-frequency ($>200\text{ cm}^{-1}$) modes (Perez-Osorio et al., 2015).

Alongside these vibrations, rotations of the organic cations within their octahedral cages are well documented and have been extensively studied (Gallop et al., 2018). These studies have largely focused on methylammonium as an A-site species, although FA based perovskites have also attracted some attention (Ghosh et al., 2017; Taylor et al., 2018). These studies have identified two regimes of rotational motion: so-called ‘wobbling within a cone’ (also sometimes referred to as ‘frustrated librations’), where the organic cations liberate around their local equilibrium positions but do not change their gross orientation, as well as ‘rotational diffusion’ where the organic cations reorient themselves along a different face of their octahedral cavity. The rapidity of these rotations is known to depend on a number of factors, including the crystalline phase (Wasylishen et al., 1985), the halide content of the inorganic lattice (Selig et al., 2017), the presence of multiple A-site species within the material (Gallop et al., 2022), and the proximity of the organic species to a material interface (Sung et al., 2020), among others. Many of these dependencies are driven by the interaction between the organic cations and the inorganic lattices; for example, the incorporation of multiple halide species and/or multiple A-site ions inhibits cation rotation, likely due to the creation of anisotropies within the cuboctahedral cavities and the alteration of the vibrational structure of the inorganic cage (Ghosh et al., 2017; Gallop et al., 2022).

The influence of the vibrational and rotational dynamics of perovskites remains an active area of investigation. The interplay between vibrational structure and carrier dynamics is particularly well documented, for example in the relaxation of hot carriers (Hopper et al., 2018) and in the modulation of charge mobilities (Munson et al., 2019). The exceptionally low phonon lifetimes of many perovskites also likely contributes the low thermal conductivity of these materials (Haeger et al., 2020). By contrast, significant debate still exists regarding the relevance of cation rotations to the optoelectronic properties of perovskites, and will likely remained unresolved in the absence of experimental techniques able to more directly probe the interaction between the organic cation and the inorganic cage (Gallop et al., 2018).

Non-linear optical properties

The non-linear optical (NLO) properties of many perovskites have also been investigated. Although this field is still developing, knowledge of the NLO properties is important for applications including lasers, photoelectric devices, and others that require high illumination intensities (Zhou et al., 2020; Xu et al., 2020). NLO properties can be distinguished by their dependence of the polarization $\mathbf{P}$ on the electric field $\mathbf{E}$ of the incident light as follows.

$$\mathbf{P} = \epsilon_0 \chi^{(1)} \mathbf{E} + \epsilon_0 \chi^{(2)} \mathbf{E}^2 + \epsilon_0 \chi^{(3)} \mathbf{E}^3 + \dots,$$

where, ϵ_0 is the dielectric constant and $\chi^{(n)}$ is the susceptibility tensor.

Second-order nonlinear processes or $\chi^{(2)}$ processes include effects such as second harmonic generation and optical rectification and require that a crystal lack inversion symmetry and thus be non-centrosymmetric. Since many perovskites have centrosymmetric cubic or tetragonal crystal structures, they do not exhibit strong second order effects. However, Ge and Sn perovskites (e.g., MASnI_3 and MAGeI_3) have shown second-order NLO effects including second harmonic generation (Zhou et al., 2020). Second order effects have also been demonstrated in perovskites which replace the B-site metal cation with a chiral organic cation that breaks the inversion symmetry of the perovskite structure (Xu et al., 2020). Centrosymmetry can also be broken by defects or at surfaces, which means that second order NLO provides a way to study important surface effects for centrosymmetric crystals (Zhou et al., 2020).

Third-order $\chi^{(3)}$ processes do not have the same requirement for non-centrosymmetry and have been more widely studied in MHPs (Zhou et al., 2020; Xu et al., 2020). The most commonly studied $\chi^{(3)}$ process in MHPs is two-photon absorption, although the optical Kerr effect, third harmonic generation, and four-wave mixing have also been observed. Generally, MHPs and especially layered perovskites have large two-phonon absorption coefficients, although reported values vary depending on sample morphology and excitation conditions, and more work is required to systematically understand the NLO properties of MHPs (Zhou et al., 2020).

Optoelectronic properties

Charge-carrier mobility

One of the benefits of metal halide perovskites for device applications is that they exhibit high charge-carrier mobilities at ambient temperatures typically on the order of $30\text{--}50\text{ cm}^2\text{V}^{-1}\text{ s}^{-1}$ as compared to other thin film materials such as metal oxides or organic

semiconductors. As compared to III–V semiconductors which typically have mobilities over $1000 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, however, charge carrier mobilities in metal halide perovskites are fairly low (Herz, 2017). Unlike many traditional semiconductors, perovskites exhibit very similar effective masses and thus mobilities for electrons and holes which enables ambipolar charge transport and facilitates charge separation (Herz, 2017). As with any semiconductor, however, the mobility of a given MHP material is sensitive to a number of extrinsic and intrinsic factors such as morphology (extrinsic) and electron-phonon interactions (intrinsic). As a result a wide range of mobilities have been reported even for films of similar compositions. However, these values can be rationalized by considering the material in its entirety with regard to both chemical composition and defect chemistry (Herz, 2017).

Extrinsic factors that affect the mobility of perovskites include its morphology, crystallinity, and defect density. For example, defects at grain boundaries have been shown to limit the mobility across thin films. As a result, local measurements of the mobility of MAPbI₃ thin films average $(37 \pm 18) \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, whereas long-range measurements across grain boundaries produce average values of $(2.4 \pm 1.1) \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ (Herz, 2017). Mobilities of $60\text{--}100 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ have been reported for MAPbI₃ single crystals, which have lower defect densities and higher crystallinity than many thin films (Herz, 2017; Xia et al., 2021). Similarly, the mobility of FASnI₃ was found to be tunable with defect density from 23 to $67 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ for films with doping densities of $7.2 \times 10^{18} \text{ cm}^{-3}$ to $2.2 \times 10^{20} \text{ cm}^{-3}$ (Milot et al., 2018).

Although most extrinsic limits to mobility can be mitigated with improved materials processing, charge-carrier mobilities in halide perovskites are also fundamentally limited due to their intrinsic properties and thus their chemical composition. Specifically, free charges in perovskites interact strongly with the perovskite lattice due to Fröhlich coupling interactions with longitudinal optical (LO) phonons (Herz, 2017). Because these interactions are relatively strong, charge-carriers in perovskites are considered to exist as large polarons (Buizza and Herz, 2021; Ghosh et al., 2020). Changing the chemical composition of the perovskite generally changes the LO phonon energy, which dictates the strength of the Fröhlich interaction and thus has a large effect on the mobility. Although changing the composition can also change the curvature of the conduction and valence band and thus the effective masses of carriers, electron-phonon interactions are believed to be the stronger determinant of charge-carrier mobility (Herz, 2017). For example, substituting lead for tin shifts the LO phonon energies to higher frequencies and thus increases the charge-carrier mobility (Milot et al., 2018).

For 2D layered perovskites and other quantum-confined materials, effective charge-carrier mobilities are lower than for 3D materials due to high exciton binding energies (Sirbu et al., 2021). For these materials, however, it is important to distinguish between the charge-carrier mobility of excitons and free charge-carriers, which exist in equilibrium at different ratios depending on the exciton binding energy and the overall carrier density (Kober-Czerny et al., 2022; Milot et al., 2016). In a prototypical PEAPbI₄ (PEA = phenylethylammonium) thin film, mobility for free charges was determined to be $8 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ and be less dependent on the polycrystalline nature of the thin film (Kober-Czerny et al., 2022). Similarly, excitons in 2D MHPs have been shown to exhibit good long-range diffusion (Sirbu et al., 2021).

Charge transport and charge-carrier recombination

Although high charge-carrier mobilities are important for efficient charge transport in a material, the diffusion length L_D of carriers in a material is also dependent on the charge-carrier lifetime $\tau(n)$ as follows

$$L_D(n) = \sqrt{\frac{\mu k_B T}{r(n)e'}}$$

where μ is the charge-carrier mobility, k_B is the Boltzmann constant, T is temperature, and e is the electronic charge (Herz, 2016). Achieving efficient charge transport thus involves minimizing the recombination rate in addition to maximizing mobility. In typical 3D perovskites with mobilities on the order of $30 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, diffusion lengths can be on the order of microns due to long charge-carrier recombination rates. It is important to note the dependence on the carrier concentration n of the overall recombination rate and thus the diffusion length. This dependence is generally expressed as

$$r(n)^- = k_3 n^2 + k_2 n + k_1,$$

where k_1 is the monomolecular recombination rate k_2 and k_3 are the rate constants for bimolecular and 3rd order or Auger recombination processes, respectively.

Monomolecular process typically involve recombination of electrons or holes with defects or traps in the MHP lattice. Reported values are thus highly sensitive to the preparation method of the perovskite material and have been shown to range from 10^9 s^{-1} (lifetime, $\tau = 1 \text{ ns}$) for highly doped tin-based perovskites to 10^6 s^{-1} ($\tau = 1 \text{ }\mu\text{s}$) for higher quality thin films (Johnston and Herz, 2016). In general, however, MHPs exhibit a surprising defect tolerance which enables thin films to have low monomolecular recombination rates despite using synthetic techniques that would promote defect formation in other types of materials. Despite this defect tolerance, defects are still a major concern for devices which operate with low charge carrier densities (such as solar cells operating at densities $\sim 10^{14}\text{--}10^{15} \text{ cm}^{-3}$) because they can limit charge transport and thus prevent devices from reaching their maximum theoretical efficiency. Although the nature of defect states in perovskites has been widely studied, uncertainties remain as to the chemical species and energetics responsible for various effects (Jin et al., 2020). One reason understanding these states is difficult is that it is common for a distribution of trap states to exist in a material (Wright et al., 2017). Additionally, defect densities are highly dependent on film processing procedures and have been shown to be influenced by the microstructure, with increased defect densities found at grain boundaries (Jin et al., 2020; Phung and Abate, 2018). A more detailed discussion of defects in perovskites can be found elsewhere (Singh et al., 2020; Stranks, 2017).

Bimolecular recombination between electrons and holes is the main mechanism for radiative recombination in perovskites. As a result, bimolecular recombination dictates the radiative efficiency $\Phi(n)$ as highlighted by the following equation.

$$\Phi(n) = \frac{r_{\text{radiative}}}{r_{\text{total}}} = \frac{nk_2}{k_1 + nk_2 + n^2k_3}$$

Values of k_2 for 3D perovskites are typically on the order of $10^{-10} \text{ cm}^3 \text{ s}^{-1}$ and are comparable to values for inorganic semiconductors including GaAs (Davies et al., 2018). Also similarly to inorganic semiconductors, bimolecular recombination has been found to be an inverse absorption process (Davies et al., 2018), so materials that exhibit strong optical absorption also have high radiative recombination rates. Due to the relationship between absorption and bimolecular radiation, differences with chemical composition are expected. However, these differences are not as dramatic as other properties as many perovskites exhibit similarly strong absorption. For example, k_2 for FASnI₃ was found to be 1×10^{-10} – $2 \times 10^{-10} \text{ cm}^3 \text{ s}^{-1}$ independent of doping density as compared to 6.8×10^{-10} for MAPbI₃ (Milot et al., 2018; Crothers et al., 2017) despite the band edge absorption energies and defect densities in these materials. However, larger differences are observed with quantum confined perovskites, as exciton formation encourages bimolecular recombination because electrons and holes are closer together, and increased k_2 values have been seen in 2D perovskites (Sirbu et al., 2021; Milot et al., 2016).

Of the three main recombination mechanisms in MHPs, Auger recombination is the least well characterized despite its importance for applications that require higher charge-carrier densities including LEDs and lasers. Reports of k_3 values for 3D perovskites are typically on the order of 0.1 – $10 \times 10^{-28} \text{ cm}^6 \text{ s}^{-1}$ and have been found to vary significantly with structural phase and chemical composition (Herz, 2016). The difficulty in characterizing Auger recombination is that it can result from many different mechanisms including charge-carrier interactions with defects, phonons, and higher-lying excited states, and more work is needed to untangle these interactions (Herz, 2016).

Other physical properties

Ion mobility

Hybrid perovskites often contain large concentrations of ionic defects that are mobile under conditions relevant to the operation of many devices. This ion mobility presents a considerable hurdle to future development of perovskite materials, both in photovoltaics and in other applications. We delineate two separate types of mobile ions within perovskites, specifically intrinsic ions that result from the presence of charged defects, as well as extrinsic ions that result from mobile dopant species. Mobile dopant species can be introduced during synthesis (either deliberately or inadvertently) or may originate from other layers within a device stack (for example, from electron/hole transport layers in solar cells).

Of the two types of defects, the intrinsic ion migration remains more broadly studied; for any crystal at a temperature of $>0 \text{ K}$, the increase in configurational entropy that results from the point defects makes their formation thermodynamically inevitable, which means that their mobility plays a strong role regardless of processing conditions and/or device implementation (Senocrate and Maier, 2019). The intrinsic defects of perovskite crystals are illustrated in Fig. 5 and almost exclusively consist of either vacancies or interstices of the A-, B- or X-site ionic species; anti-site defects are predicted to be unstable and to quickly collapse into a vacancy

Fig. 5 Cartoon illustrating different defect types in hybrid perovskites, including an iodine vacancy (a), antisite defects (b), an MA vacancy (c), and MA and iodine interstitials (d and e). An identical set of defects could also be present for the Pb ions but are not displayed here for clarity.

and interstitial. The relative concentration(s) of these different defects can be estimated through application of mass-action laws combined with appropriate constraints to account for electroneutrality (Moia and Maier, 2021), while their mobilities can be estimated from *ab initio* calculations (Azpiroz et al., 2015; Eames et al., 2015). *Ab Initio* calculations typically extrapolate mobilities by treating the macroscopic movement of ionic defects as a sequence of thermally activated hops between adjacent sites, the frequency of which is related to an energetic barrier *via* an Arrhenius type relation. The results of these *ab initio* ‘hopping’ studies have implicated the migration of halide defects (both vacancies and interstitials) as the dominant cause of ionic mobility (Azpiroz et al., 2015; Eames et al., 2015). It is important to recognize however that a simple Arrhenius-type relation neglects other processes within the material (e.g., formation of defect complexes, temperature dependent charge carrier concentrations, etc.) (Senocrate and Maier, 2019). Nevertheless, subsequent experimental studies have further identified halide vacancies as the dominant mobile ionic species, validating earlier *ab initio* studies and demonstrating their utility in studying ionic mobility (Senocrate et al., 2017; Yang et al., 2015; Eames et al., 2015). Recent efforts have continued to build on these earlier findings by considering both electronic and ionic mobility, enabling links between ionic mobility and the performance of hybrid perovskite optoelectronics to be studied (Calado et al., 2022).

By contrast, while extrinsic mobile ions (such as Li^+) are also known to be important in the behavior of hybrid perovskite devices (Li et al., 2017b), they are less extensively studied and the thermodynamics and kinetics of their underlying processes is less well understood and more challenging to characterize, potentially owing to the diversity of different potential dopants (Senocrate et al., 2018; Park et al., 2018; Ceratti et al., 2020), as well as co-operative effects in which certain extrinsic species can act to enhance the mobility of ionic defects (Ceratti et al., 2020; Jong et al., 2018). Nevertheless, several studies have further highlighted the undesirable nature of extrinsic ions for solar cells containing perovskites and have emphasized the importance of further study of extrinsic ion migration with a view to either mitigating the amount of ion migration or else mitigating the effect of extrinsic ion migration (Domanski et al., 2016; Jong et al., 2018).

The most immediately apparent of these effects is the well-documented hysteresis of the J-V curves of certain hybrid perovskites, which is now known to be due at least partially to bias-induced migration of ionic defects. Hysteresis can lead to significant errors in the reporting of J-V characteristics and can even be exploited to artificially inflate solar cell performance figures; for this reason, it is essential to carefully control the conditions under which the J-V curves are acquired, including scan rate and direction, pre-biasing, and light soaking (Kim et al., 2015). Moreover, the formation of a space-charge layer close to the electron/hole contacts by mobile ions is known to strongly inhibit charge collection and so reduce device performance (Kim et al., 2020). Moreover, mobile ionic defects act as charge traps, leading to a strongly nonlinear relationship between carrier dynamics and the movement of intrinsic defects. Finally, ionic mobility can also lead to long-term degradation issues, for example through excorporation of halide species, or else through photoinduced demixing in mixed halide species, which further limits the lifetime of these materials (Moia and Maier, 2021). By contrast, the exotic switching physics that arise from ion migration is an avenue for new technological applications; for example, in next-generation hardware security (John et al., 2021) and biomimetic computing (Gogoi et al., 2021), among others.

Thermal properties

In addition to their optical and electronic properties, the thermal properties of perovskites are interesting to consider for device applications. In general, perovskites have low heat capacities, low thermal conductivities, and high thermal expansion coefficients at ambient temperature (Haeger et al., 2020). They don’t behave like traditional semiconductors in this respect but instead have properties more similar to insulators like glass (Haque et al., 2020). Thermal conductivity is the parameter reported for the widest range of perovskite materials. Values for MAPbI_3 are on average $0.35 \text{ W m}^{-1} \text{ K}^{-1}$, and most materials fall in the range of $0.1\text{--}0.5 \text{ W m}^{-1} \text{ K}^{-1}$. These values are low because heat transport in perovskites occurs mainly via phonons, which exhibit strong phonon-phonon scattering interactions that limit heat transport, similarly to how electron-phonon interactions limit the transfer of charge (Haque et al., 2020). More specifically, the group velocity of acoustic phonons is low and the optical phonons have short lifetimes ($<100 \text{ ps}$) and short mean free paths ($<10 \text{ ps}$) in MHPs, resulting in inefficient heat transport.

As with most perovskite properties, the thermal properties are tunable with perovskite composition and morphology. Additionally, thermal properties are highly temperature dependent and also sensitive to structural phase changes (Haeger et al., 2020). For example, thermal conductivities can vary significantly due to phonon scattering by defects, which decreases the phonon mean free path. Accordingly, lower thermal conductivities have been observed at grain boundaries in thin-film MHPs. Halide perovskite nanomaterials including quantum dots also exhibit lower thermal conductivities because the mean free path of phonons is limited to $\sim 100 \text{ nm}$ by their geometry. 2D layered perovskites also have lower thermal conductivities than their 3D analogs because of both geometric confinement and decreased phonon propagation across the organic layers. An exception to the mean free path argument is the observation of increased thermal conductivities for the series $\text{MAPbI}_3\text{--MAPbBr}_3\text{--MAPbCl}_3$ as the mean free path of phonons in these materials is similar. In this case, the differences are likely the results of differences in the sound velocity and heat capacity of the materials. Although changes in thermal conductivity have been observed for A-site cation substitution, there is debate about origin of these changes, and results from theoretical studies and experiments often disagree (Haque et al., 2020).

Applications

The unique physical and chemical properties of MHPs have been the main driver for the interest in their development for devices. Due to their many similarities to inorganic semiconductors, the main areas of interest are those in which materials such as silicon and GaAs have traditionally dominated. These applications include solar cells (Ali et al., 2021; Green et al., 2014), light emission

(Lei et al., 2021; Veldhuis et al., 2016), and other electronics such as field-effect transistors (Younis et al., 2021). The following section summarizes some of these main applications of MHPs but also highlights some of the emerging applications including photocatalysis (Ren et al., 2022) and thermoelectric generators (Haque et al., 2020) in order to showcase the potential range of MHP applications.

Photovoltaic cells

The production of efficient photovoltaic cells is one of the biggest driving forces for MHP research. In just over a decade of development, perovskite solar cells rival market-leading silicon technologies; according to the best research-cell efficiency chart published by the US National Renewable Energy Lab (NREL), the current record power conversion efficiency (PCE) is 25.7% for a perovskite-based solar cell compared to 26.7% for a crystalline silicon cell (NREL, 2021; Min et al., 2021).

Due to their strong visible absorption and relatively high charge-carrier mobility, MHPs form the active layers solar cells and are thus responsible for solar light absorption and for facilitating initial charge separation. They are usually deposited as thin films in solar devices, but other morphologies have also been studied; examples of more exotic hybrid perovskite PV devices include solar cells that use perovskite nanowires (Im et al., 2015), as well as devices that employ sophisticated nanostructured architectures (Tooghi et al., 2020). A diagram and cross-sectional SEM of a typical perovskite solar cell is given in Fig. 6a and b which shows a perovskite layer sandwiched between a hole transport material (HTM) and electron transport material (ETM). In typical devices, the perovskite layer is on the order of 300–500 nm thick (Fig. 6b), which is sufficient to absorb most of the incoming solar radiation. Following light absorption by the perovskite, charges are separated by the energy gradient produced by the HTM and ETM on either side of the perovskite. This charge separation is possible without additional engineering of the perovskite film (e.g., a p-n junction as in silicon solar cells or a bulk heterojunction as in organic solar cells) because perovskites exhibit high, ambipolar mobilities and the diffusion length of carriers is greater than the thickness of the film. Following charge separation, the circuit is completed by metal

Fig. 6 Hybrid perovskite devices. (a and b) diagram (a) and SEM cross-section (b) of a hybrid perovskite solar cell. Similar device architectures find use in applications beyond solar cells, as in the hybrid perovskite LEDs shown in (c). Subfigure (b) reproduced with permission from Li CW, Zhou YY, Wang L, Chang Y, Zong YX, Etgar L, Cui GL, Padture NP and Pang SP (2017a) Methylammonium-mediated evolution of mixed-organic-cation perovskite thin films: A dynamic composition-tuning process. *Angewandte Chemie, International Edition* 56: 7674–7678.; (c) is adapted courtesy of Zhi-Kuang Tan/University of Cambridge.

and transparent conducting electrodes. Much research effort has been dedicated to optimizing materials synthesis and device fabrication techniques in order to enable high efficiency devices, and the reader is referred to several more specific reviews for further information (Ali et al., 2021; Green et al., 2014; Sirbu et al., 2021).

The theoretical limit for the efficiency of a single junction solar cell such the one described previously is $\sim 33\%$, but this limit increases to 42% for a tandem solar cell which employs two absorbers with different bandgaps chosen to maximize solar absorption while minimizing thermalization losses (Li and Zhang, 2020). The bandgap tunability of perovskites over the visible region makes them attractive for the development of such tandem cells. For example, substituting bromide into FAPbI_3 to form mixed halide perovskites of the form $\text{FAPb}(\text{I}_y\text{Br}_{1-y})_3$ can tune the bandgap from 1.48–2.23 eV (Eperon et al., 2014), encompassing the optimum range for the wide bandgap materials for tandem solar cells. Similarly, replacing tin with lead pushes the bandgap closer to the optimized bandgap for a single junction (1.34 eV), and mixing tin and lead can further tune the bandgap between 1.2 eV and 1.4 eV, including the optimum value for the low bandgap absorber for a two-layer tandem solar cell (Moot et al., 2020; Konstantakou and Stergiopoulos, 2017). Accordingly, perovskite-perovskite tandem solar cells have been fabricated using such materials, although reported efficiencies are still below single-junction cells and more development is needed (Ho-Baillie et al., 2021). However, more progress has been made with perovskite-Si tandem cells due to their potential to be integrated with exiting manufacturing, and efficiencies up to 31.3% have been reported (NREL, 2021).

Water oxidation and other catalysis

Metal halide perovskites have also been investigated for their photocatalytic activity (Ren et al., 2022) due to their known ability to efficiently harness light energy and transport charge. One potential application is artificial photosynthesis, where sunlight is used to split water into molecular hydrogen and oxygen. In photoelectrochemical cells for water splitting, perovskites have incorporated into both the photo-cathode for oxygen generation and photo-anode for hydrogen generation. Analogously, perovskites have also been used for CO_2 reduction and for the reduction of HX to H_2 . There have also been reports of using perovskites for other photochemical reactions such as the degradation of pollutants including methyl orange, methylene blue, and rhodamine B and organic synthesis including the oxidation of benzylic alcohols to aldehydes and C—H bond activation. Although some perovskite-based photocatalytic devices have shown good reactivity, stability has been limited to hours or days due to the stability of the perovskite material in aqueous environments (see “Key issues”). As compared to solar cells, perovskite photocatalysis is much a newer sub-field, and there is more opportunity for significant improvements in performance.

Light emission

The second most popular application for perovskites after solar cells is light emission for both light-emitting diodes (LEDs) and lasers.

LEDs are essentially a solar cell running in reverse, where charge-carriers are injected into a material and light is emitted as the carriers recombine radiatively. Therefore, factors which make perovskites suitable for solar cells, such as high charge-carrier mobilities and strong light absorption, mean that perovskites also make good LEDs. There is the additional qualification for LED materials to exhibit a high photoluminescence quantum yield (PLQY). A high PLQY can be achieved by minimizing nonradiative recombination processes included trap-assisted and Auger recombination processes, allowing the dominant recombination mechanism to be radiative, bimolecular recombination. In practice, this balance entails engineering materials with low monomolecular and Auger recombination rate constants and high bimolecular recombination rate constants. As the bimolecular rate constants for 3D perovskites are not particularly high (therefore putting a larger burden on minimizing monomolecular recombination), 2D layered perovskites and quantum dots have seen more application in perovskite LEDs (PeLEDs) as quantum confinement in these materials lowers the separation between electrons and holes, thus promoting bimolecular recombination.

For the best perovskite LEDs, external quantum efficiencies (EQEs) of over 23% have been reported, which make perovskites competitive with other semiconductor and organic LED technologies (Fakharuddin et al., 2022). Furthermore, the bandgap tunability of perovskites has resulted in the fabrication of devices emitting at wavelengths from the ultraviolet to near-infrared, with the most efficient devices emitting green and red wavelengths (Fig. 4). Perovskite LEDs also exhibit good color purity due to their relatively narrow emission spectra.

Lasing applications also rely on the promotion of bimolecular recombination over other charge deactivation processes (Lei et al., 2021). Again, factors including strong absorption and low defect densities are important for efficient lasing with the added requirement of high optical gain to promote population inversion in the material following the injection of charge-carriers (either through optical or electrical pumping). A simple measure of the potential for high optical gain is the threshold for amplified spontaneous emission, which manifests as a narrowing of the PL peak as population inversion is achieved. Perovskites have demonstrated ASE thresholds as low as $4 \mu\text{J}/\text{cm}^2$, although they are highly dependent on a number of factors including the chemical composition, defect density, and morphology of the material. Most commonly pumped with ultrafast lasers, a number of perovskite laser resonators have been reported for a range of wavelengths throughout the visible spectrum and into the near-infrared. Additionally, optically pumped continuous wave (CW) lasers have been fabricated, which has historically been a challenge for solution-processed semiconductors. Although electrically driven lasers have not yet been demonstrated due to issues with heating and photoinduced defects, quasi-2D MHP materials show promise for this application due to their low ASE threshold and energy landscape beneficial to enabling population inversion (Lei et al., 2021).

Other electronics

MHPs have also been investigated for a range of other electronic applications including transistors and nonvolatile resistive switching (RS) memories (Younis et al., 2021). They are attractive for these applications for similar reasons as optoelectronics including high charge-carrier mobility, ambipolar charge transport, and low defect density. In fact transistors were one of the first applications investigated in the 1990s for 2D perovskites, and their development continues, benefiting from the compositional engineering used to optimize perovskite materials for other applications. Additionally, perovskites have shown promise for use in memory devices. These devices rely on a property of MHPs that is usually considered detrimental to device efficiency, namely the electrical hysteresis that exists due to their facile ion mobility. The most commonly used perovskites for resistive random-access memory (RRAM) devices are therefore 3D perovskites such as MAPbI₃ and MAPbBr₃ which exhibit strong ion migration. Although these devices are still at an early stage of development, their performance is already competitive with existing devices, showing promise for the future development of this field.

Thermoelectric generators

Other applications use the unique heat and electrical transport properties of MHPs to their advantage to convert heat electrical energy in thermoelectric generators (Haeger et al., 2020; Haque et al., 2020). Although the performance of perovskite-based thermoelectric generators is on par with versions utilizing organic materials, efficiencies are still significantly lower than the best inorganic materials such as Bi₂Te₃ (Haque et al., 2020). However, MHPs remain promising for these applications because they have low thermal conductivities coupled with high charge-carrier mobilities and large Seebeck coefficients.

Key issues

Stability

Stability has been aptly called the Achilles heel of MHPs (Moot et al., 2020), as many materials can irreversibly degrade in the presence of four major environmental factors: moisture, oxygen, light, and heat (Wang et al., 2016). This degradation is a significant problem given their potential application in devices such as solar cells, which need to operate under a variety of conditions.

Degradation occurs in both dry air and moist O₂ free conditions, indicating that O₂ and H₂O mechanisms of degradation are separate—one does not require the other (Bryant et al., 2016). For MAPbI₃, the weakness is the organic cation, and degradation in both cases occurs through attack of the A-site ion. In the case of oxygen degradation, this occurs via the photocatalytic generation of superoxide ions (O₂^{•−}) (Aristidou et al., 2015). For water degradation, it is believed that attack of the A-site ion proceeds via deprotonation of the ammonium moiety, followed by transfer of the proton to the iodine ion. For water induced degradation, this proceeds via:

MAPbI₃ hydrates can also form through water ingress, disrupting the 3D crystal structure and facilitating further degradation as described above (Leguy et al., 2015).

Perovskites also degrade at moderately high temperatures not too far above ambient temperatures (Wang et al., 2016). Additionally, the low thermal conductivities of perovskites mean that the materials cannot easily dissipate heat (for example under prolonged solar irradiation), and local temperatures could be higher in the materials, further promoting degradation. Temperature changes can also alter many properties of perovskite materials including their charge-carrier mobilities and recombination dynamics (Milot et al., 2015). Having high temperature fluctuations in devices which have been optimized at a specific temperature could therefore decrease their efficiency operating under different conditions if heat dissipation is not properly managed.

Light sensitivity is not only a manifestation of poor thermal transport but is also a catalyst for chemical degradation processes. Furthermore, it has been shown to be related to a range of film characteristics including ion migration and defect density (Chen et al., 2021). For example, light sensitivity is a particular challenge for mixed-halide materials like FAPb(I_yBr_{1-y})₃ as illumination promotes halide segregation, leading to the formation of regions in the film which are either iodide or bromide rich (Hoke et al., 2015). This rearrangement alters the energy landscape such that charge-carriers are funneled to the lower energy iodide-rich regions inhibiting efficient charge transport in devices (Knight and Herz, 2020).

For device applications, some atmospheric instabilities, including degradation from humidity and oxygen exposure, can be avoided by encapsulating whole devices or device layers with a material that is impermeable to these species but does not significantly impeded device performance (Li et al., 2021b; He et al., 2020; Lin et al., 2018). Similarly, thermal instability could be improved via heat management techniques, although low thermal conductivities make this approach challenging (Haeger et al., 2020). Light instability is a bigger problem, however, since it is central to the operation of optoelectronic devices and thus requires careful materials engineering to resolve.

As a result, several strategies have been implemented to improve the stability of the perovskite layer itself including mixing A-site cations, increasing grain size, and treating with passivating agents (Knight and Herz, 2020). For example, perovskite stability to water can be improved partially by substitution with less acidic A-site species, such as formamidinium (Aristidou et al., 2015), and 2D layered perovskites are substantially more stable than their 3D counterparts due to the hydrophobic cations blocking water

ingress and suppressing ion migration (Sirbu et al., 2021). Passivation of grain boundaries has also been shown to improve stability by reducing water ingress (Qin et al., 2020), and/or by passivating X-site vacancies that would otherwise drive defect-induced degradation processes discussed in previous sections (Li et al., 2021a). However, the exact mechanisms underlying many improvement strategies are still unclear largely because changing one aspect of the film can change a number of its properties including morphology, crystallinity, defect density, and band structure (Knight and Herz, 2020; Rehman et al., 2017; Rehman et al., 2015), and more research is needed to develop and understand stable perovskites for device applications.

Toxicity

Another key challenge for MHPs is that lead is a highly toxic substance. Although devices such as perovskite solar cells use very thin films with only a partial lead component, even these amounts could have environmental and health impacts when used on an industrial scale (Goetz et al., 2021; Babayigit et al., 2016). Lead leakage into the environment could be mitigated through encapsulation and recycling strategies (Li et al., 2021b; Goetz et al., 2021), but finding a non-toxic replacement would be a more permanent and reliable solution. Although a range of perovskite and perovskite-like materials have been identified to replace lead-based materials, these options tend to improve toxicity at the expense of either efficiency or facile processability (Huang et al., 2021). For example, chalcogenide perovskites such as (e.g., BaZnS_3) have demonstrated good optoelectronic properties but complicated processing at high temperatures makes them unattractive for large scale commercialization. Among all of the options, tin-based perovskites have shown the most promise, despite some similar concerns about their toxicity and stability (Goetz et al., 2021).

Understanding fundamental properties

Because MHPs have been developed so rapidly for device applications, the understanding of their fundamental properties has lagged behind, especially since they exhibit a unique set of properties (e.g., high charge-carrier mobilities but low thermal conductivities) that makes characterization according to existing materials classes difficult. Furthermore, sample-to-samples variations and the dependence of properties on many extrinsic factors such as defect density make fundamental studies challenging. Although a range of properties are currently being discussed in the literature including ferroelectricity (Zhou et al., 2018), polarons (Ghosh et al., 2020), and entropy (Martiradonna, 2018), we have chosen to discuss just a couple of examples to highlight the main arguments at the heart of many of these disputes.

One unanswered question in MHP research is the relationship between the chemical composition of a perovskite material (including defects) and its optoelectronic properties. As a result, it is not unusual to see contrasting reports in the literature as the field attempts to pinpoint these underlying mechanisms. For example, halide migration in mixed halide perovskites has been attributed to both extrinsic factors such as crystallinity and crystal size and intrinsic factors related to coupling of charge-carriers to the crystal lattice (Knight and Herz, 2020). The difficulty with these analyses hinges on the fact that perovskite thin films, which are the most widely studied, are polycrystalline materials containing grain boundaries and grains. A high degree of heterogeneity can exist among grains both in terms of their defect concentration and crystallinity, and optoelectronic properties including the photoluminescence quantum yield and Raman vibrational modes have been shown to vary significantly from grain to grain (Petrus et al., 2017). Because the nanostructured properties can be difficult to characterize, the influence of this heterogeneity on bulk charge transport properties has remained elusive (Petrus et al., 2017).

Cation rotation—in particular its relevance toward the optoelectronic properties and device performances of hybrid perovskites—is also highly controversial. Early theoretical studies invoked the orientational disorder of the organic species in hybrid perovskites to explain their surprisingly low recombination velocities (Ma and Wang, 2015; Frost et al., 2014), however more recent experimental determinations of cation rotational mobility strongly indicate that the long-lived orientational ordering necessary for effective segregation of electrons and holes was highly unlikely (Gallop et al., 2018). Other theoretical studies have suggested that orientationally mobile organic cations can act to ‘solvate’ electrons and holes, providing an additional barrier to carrier recombination and thus explaining the relatively large carrier diffusion lengths despite relatively low mobilities (Bonn et al., 2017; Zhu and Podzorov, 2015). However, these ideas appear incompatible with experimental observations of similar recombination rates in halide perovskites incorporating inorganic Cs ions as their A-site species (Zhu et al., 2017; Kulbak et al., 2015). More recently, ultrafast spectroscopy experiments have focused on the interactions between the organic cation and the inorganic lattice (Grechko et al., 2018), although the influence of this interaction on the electronic properties of the perovskite is yet to be fully understood.

Conclusion

Metal halide perovskites have attracted much attention in recent years due to their potential applications and their interesting physical properties. This interest has arisen because MHPs have electronic properties which resemble traditional semiconductors like GaAs and silicon but can be more easily synthesized using either solution processing or vapor-based techniques. Furthermore, they offer straightforward tunability of their optoelectronic properties so that they can be tailored for the specific application. As a result, many applications have been successfully developed, both based entirely on MHPs or using MHPs to boost the efficiency of existing devices (i.e., tandem solar cells). The list of applications is ever expanding from photocatalysis to memory devices and beyond.

However, perovskites have some major issues that need to be solved, namely their toxicity and stability, before they can realize their full potential. As such, solving these problems continues to be a major focus in the field. Alongside this effort, researchers are also seeking to better understand the fundamental properties of MHPs in order to better inform device design and better understand a material that defies characterization according to existing systems.

Abstract

Particle science and technology is a rapidly developing interdisciplinary research area with its core being the understanding of the relationships between micro- and macro-scopic properties of granular matter—a state of matter that is widely encountered but poorly understood. The macroscopic behavior of particulate matter is controlled by the interactions between individual particles as well as interactions with surrounding gas, liquid and/or wall. Understanding the microscopic mechanisms in terms of these interaction forces is therefore key to leading to truly interdisciplinary research into particulate matter and producing results that can be generally used. This aim can be effectively achieved via particle scale research based on detailed microdynamic information such as the forces acting on and trajectories of individual particles in a considered system. In recent years, such research has been rapidly developed worldwide, mainly as a result of the rapid development of discrete particle simulation technique and computer technology. This chapter presents an overview of the work in this direction. It is demonstrated that simulation and modeling has emerged to be a powerful tool not only for fundamental research but also for engineering application.

Nomenclature

C_n	Coordination number, dimensionless
d	Diameter of particles, m
f	Force acting on a particle, N
g	Gravitational acceleration, ms^{-2}
H	Hamaker constant, Nm
I	Moment of inertia of a particle, defined as $I = 2/5 mR^2$, kgm^2
k_c	Number of particles in a computational cell, dimensionless
k_i	Number of particles interacting with particle i , dimensionless
m	Mass of a particle, kg
N	Total number of particles in a considered system, dimensionless
p	Pressure, Pa
R	Radius vector of a particle, m
Re	Reynolds number, dimensionless
t	Time, s
T	Torque acting on a particle, Nm
u	Fluid velocity, ms^{-1}
v	Translational velocity of a particle, ms^{-1}
z	Separation distance between two interacting surfaces, m
z_0	Smallest separation distance between two interacting surfaces, m
ΔV	Volume of a computational cell, m^3

Greek letters

δ	Displacement between two contacting particles, m
ϵ	Porosity, dimensionless
γ	Friction coefficient, dimensionless
ρ	Density, kgm^{-3}
τ	Fluid viscous stress tensor, $\text{kgm}^{-1} \text{s}^{-2}$
μ	Viscosity, $\text{kgm}^{-1} \text{s}^{-1}$
η	Viscous contact damping coefficient of a particle, kgs^{-1}
κ	Spring constant of a particle, Nm^{-1}
ω	Rotational velocity of a particle, s^{-1}
ζ	Arbitrary variable used in averaging operators

Subscripts

c	Contact
d	Damping
f	Fluid phase
i	Particle i
ij	Between particles i and j
n	Normal component
p	Particle phase
pf	Particle-fluid
pp	Particle-particle
r	Rolling friction
s	Sliding friction
t	Tangential component
v	van der Waals

Averaging operator

$\langle \rangle$ Ensemble-average, defined as $\langle \zeta \rangle = \frac{1}{N} \sum_{i=1}^N \zeta_i$

Introduction

Granular materials, which can be either wet or dry and range in size from nanometers to centimeters, are widely encountered as particles or powder in industries and in nature (Bideau and Hansen, 1993; Herrmann et al., 1997; Mehta, 1993; Oda and Iwashita, 1999; Seville et al., 1997). As with solids, they can withstand deformation and form heaps; as with liquids, they can flow; as with gases, they exhibit compressibility. Corresponding to the fluid- and solid-like modes, they show different flow regimes: quasi-static regime, rapid flow regime and a transitional regime that lies in between. These features give rise to another state of matter that is poorly understood. Development of a general theory to describe the packing (statics) and flow (dynamics) of granular materials has been a problem challenging the scientific community for years.

Essentially, the existing approaches to modeling granular materials can be classified into two categories: the continuum approach at a macroscopic level and the discrete approach at a microscopic level. In the continuum approach, the macroscopic behavior is described by balance equations, e.g., mass and momentum as used in the Two Fluid Model (TFM), closed with constitutive relations together with initial and boundary conditions (Gidaspow, 1994; Crowe et al., 1998). This approach is preferred in process modeling and applied research because of its computational convenience. However, its effective use heavily depends on constitutive or closure relations and the momentum exchange between particles of different types. In the past, different theories have been devised for different materials and for different flow regimes. For example, models have been proposed to derive the constitutive equations for the rate-independent deformation of granular materials based on either the plasticity theory or the double shearing theory; rapid flow of granular materials has been described by extending the kinetic theory of dense gases; the transitional regime that involves both collisional and frictional mechanisms is studied by use of the kinetic theory combined with the Mohr-Coulomb quasi-static theory (Bideau and Hansen, 1993; Herrmann et al., 1997; Oda and Iwashita, 1999). However, to date, there is no accepted continuum theory applicable to all flow conditions. As a result, phenomenological assumptions have to be made to obtain the constitutive relations and boundary conditions, which have very limited application.

The discrete approach is based on the analysis of the motion of individual particles and has the advantage that there is no need for global assumptions on the solids such as steady-state behavior, uniform constituency, and/or constitutive relations. Various methods have been developed in the past. A major type of discrete approach is based on the so-called Discrete Element Method (DEM) originally developed for rock mechanics. The method considers a finite number of discrete particles interacting by means of contact and non-contact forces, and every particle in a considered system is described by Newton's equations of motion (Herrmann et al., 1997; Oda and Iwashita, 1999). In principle, it is similar to molecular dynamic simulation (MDS) but the forces involved differ because of the difference in time and length scales (Israelachvili, 1991; Xu and Yu, 1997). DEM-based simulation has been recognized as an effective method to study the fundamentals of granular materials and assess the performance of industrial processes. By means of a proper average method, it can also generate information to support continuum modeling.

This chapter is focused on the discrete approach. It first describes the principles and key features of the simulation method, and then discusses its application to the study of a few typical static and dynamic particle systems. Emphasis will be given to the validity analysis and the usefulness of the resulting particle scale information in elucidating the fundamentals of granular materials, achieved through illustrative examples.

Simulation method

Governing equations

A particle in a considered system can have two types of motion: translational and rotational, determined by Newton's second law of motion. During its movement, the particle may collide with its neighbor particles or wall at the contact points and interact with the surrounding fluid, through which the momentum and energy are exchanged. For the systems considered in this article, at any time t , the equations governing the translational and rotational motions of particle i are (Xu and Yu, 1997; Zhou et al., 1999; Yang et al., 2000)

$$m_i \frac{dv_i}{dt} = f_{pf,i} + m_i g + \sum_{j=1}^{k_i} (f_{c,ij} + f_{d,ij} + f_{v,ij}) \quad (1)$$

and

$$I_i \frac{d\omega_i}{dt} = \sum_{j=1}^{k_i} (T_{c,ij} + T_{r,ij}) \quad (2)$$

where m_i , I_i , v_i and ω_i are, respectively, the mass, moment of inertia, translational and rotational velocities of the particle. The forces involved are: the particle-fluid interaction force, $f_{pf,i}$, gravitational force, $m_i g$, and interparticle forces between particles i and j . The torques include the interparticle torque $T_{c,ij}$ and rolling friction torque $T_{r,ij}$. For multiple interactions, the interparticle forces and torques are summed for k_i particles interacting with particle i .

Particle flow is often coupled with fluid (gas and/or liquid) flow. Various approaches have been proposed to simulate such a coupled particle-fluid flow. The time and length scales for fluid flow can range from discrete (MDS, Lattice Boltzman (LB), Pseudo-particle (PP)) to continuum (Direct Numerical Simulation (DNS), Large Eddy Simulation (LES), and other conventional techniques like TFM) description. These methods have been widely used in Computational Fluid Dynamics (CFD) (Gidaspow, 1994; Crowe et al., 1998; Zhu et al., 2007; Rong et al., 2014; Wu et al., 2021). Relative to particle phase, they can also be categorized into three groups: sub-particle, pseudo-particle and computational cell. Table 1 lists a few representative combinations of different length scales for fluid and particle phases and their relative merits in different aspects.

At this stage of development, the difficulty in particle-fluid flow modeling is mainly related to solid phase rather than fluid phase. Therefore, the so-called combined continuum and discrete model (CCDM) or CFD-DEM is attractive because of its computational convenience as compared to DNS or LB-DEM and capability to capture the particle physics as compared to TFM. In CCDM, the continuum fluid field is calculated from the continuity and the Navier-Stokes equations based on the local mean variables over a computational cell, which are given by (Xu and Yu, 1997; Zhou et al., 2010)

$$\frac{\partial \varepsilon}{\partial t} + \nabla \cdot (\varepsilon \mathbf{u}) = 0 \quad (3)$$

and

$$\frac{\partial (\rho_f \varepsilon \mathbf{u})}{\partial t} + \nabla \cdot (\rho_f \varepsilon \mathbf{u} \mathbf{u}) = -\nabla p - F_{pf} + \nabla \cdot (\varepsilon \boldsymbol{\tau}) + \rho_f \varepsilon \mathbf{g} \quad (4)$$

where $\mathbf{u}$, p and $\boldsymbol{\tau}$ are, respectively, the fluid velocity, pressure and viscous stress tensor; $F_{pf} = \left(\sum_{i=1}^{k_c} f_{pf,i} / \Delta V \right)$ is the particle-fluid interaction force, and ε , ΔV and k_c are respectively the porosity, volume and number of particles in a computational cell.

Models for particle-particle and particle-fluid interactions

The forces acting on a particle result from particle-particle and particle-fluid interactions. For particles, these interactions include the forces due to direct or non-direct contacts between particles, as shown in Fig. 1. The direct contact forces include the contact force and viscous contact damping force. The non-direct contact forces include the forces associated with fine particles such as the van der

Table 1 Typical models for particle-fluid flow and their relative merits.

<i>Model type</i>				<i>Closure of equations</i>	<i>Incorporation of distribution effects of dispersed, solid phase</i>	<i>Computational effort</i>	<i>Suitability for engineering application in relation to process modeling and control</i>	<i>Suitability for fundamental research in relation to fluid physics</i>
<i>Length scale for fluid phase</i>	<i>Length scale for particle phase</i>	<i>Nature of coupling</i>	<i>Example</i>					
Sub-particle (discrete or continuum)	Particle (discrete)	Discrete +discrete or continuum +discrete	LB-DEM or DNS	Yes (but may experience numerical difficulty for systems with strong particle-particle interactions)	Yes	Extremely demanding	Extremely difficult	Most acceptable (f_{pf} can be used for CCDEM)
Pseudo-particle (discrete)	Particle (discrete)	Discrete +discrete	PP-DEM	No (difficulty to determine physical properties of a pseudo-particle)	Yes	Very demanding	Very difficult	Acceptable (but only valid for well defined PP system)
Computational cell (continuum)	Particle (discrete)	Continuum + discrete	CCDM or CFD-DEM	Yes	Yes	Demanding	Difficult	Acceptable
Computational cell (continuum)	Computational cell (continuum)	Continuum + continuum	TFM	No (constitutive relation for solid phase and phase interactions not generally available)	No	Acceptable	Easy	No

Fig. 1 Schematic illustration of the forces acting on particle i from contacting particle j and non-contacting particle k (Yang et al., 2000).

Table 2 Components of forces and torque acting on particle i .

Force or torque		Symbol	Equation
Normal forces	Contact	$\mathbf{f}_{cn, ij}$	$-\kappa_i \delta_{c, ij}$
	Damping	$\mathbf{f}_{dn, ij}$	$-\eta_i \mathbf{v}_{n, ij}$
Tangential forces	Contact	$\mathbf{f}_{ct, ij}$	$\min(\gamma_s f_{cn, ij}, \kappa_i \delta_{t, ij}) \frac{\delta_{t, ij}}{\delta_{t, ij}}$
	Damping	$\mathbf{f}_{dt, ij}$	$-\eta_i \mathbf{v}_{t, ij}$
Torques	Interparticle	$\mathbf{T}_{c, ij}$	$\mathbf{R}_i \times (\mathbf{f}_{ct, ij} + \mathbf{f}_{dt, ij})$
	Rolling friction	$\mathbf{T}_{r, ij}$	$-\gamma_r R_i \mathbf{f}_{cn, ij} \hat{\omega}_i$
Gravity force		$\mathbf{G}_i$	$m_i \mathbf{g}$
van der Waals force		$\mathbf{f}_{v, ij}$	$\frac{Hd}{6[\max(z, z_0)]^2} \frac{R_i}{R_j}$
Fluid drag force		$\mathbf{f}_{pf, i}$	$0.5 c_{d0, i} \rho_f \pi R_i^2 c_i^2 u_i - v_i (u_i - v_i) e_i^{-(\chi + 1)}$

where: $\mathbf{V}_{ij} = \mathbf{V}_j - \mathbf{V}_i + \boldsymbol{\omega}_j \times \mathbf{R}_j - \boldsymbol{\omega}_i \times \mathbf{R}_i$, $\mathbf{V}_{n, ij} = (\mathbf{V}_{ij} \cdot \mathbf{n}) \mathbf{n}$, $\mathbf{V}_{t, ij} = (\mathbf{V}_{ij} \times \mathbf{n}) \times \mathbf{n}$, $\hat{\omega}_i = \frac{\boldsymbol{\omega}_i}{\omega_i}$, $\mathbf{n} = \frac{\mathbf{R}_i}{R_i}$, $\chi = 3.7 - 0.65 \exp \left[-\frac{(1.5 - \log_{10} Re_{pi})^2}{2} \right]$,
 $c_{d0, i} = \left(0.63 + \frac{4.8}{Re_{pi}^{0.5}} \right)^2$, $Re_{pi} = \frac{2\rho_f R_i |u_i - v_i|}{\mu_f}$

Waals force, electrostatic force, capillary and viscous forces, and solid bonding forces (Israelachvili, 1991; Sun et al., 2013). Particle-fluid interactions include buoyancy, drag force, and so on (Crowe et al., 1998; Rong et al., 2014; Wu et al., 2021; Zhou et al., 2010). These forces have been implemented by various investigators in various ways. To date, the equations to determine some of the forces are not fully developed. Therefore, to develop a more comprehensive theory and experimental techniques to quantify the interaction forces between particles and between particle and fluid under various conditions will continue to be an active research area for years to come. Table 2 lists the equations employed to calculate the forces and torques for the particle systems considered in this chapter; they are also commonly used in the literature (Xu and Yu, 1997; Zhou et al., 1999; Yang et al., 2000; Zhu et al., 2007; Rong et al., 2014; Wu et al., 2021; Zhou et al., 2010).

Numerical solution and boundary treatments

Eqs. (1) and (2) for solid flow can be solved by an explicit time integration method and Eqs. (3) and (4) for fluid flow by use of a standard CFD algorithm, facilitated with suitable boundary conditions. For the fluid phase, the no-slip boundary condition often applies to bed walls, together with other (inlet or outlet) conditions specified. For the particle phase, the interparticle force models are also applied to the interaction between a particle and a wall, with the corresponding wall properties used; however, the wall is assumed to be so rigid that no displacement and movement of the wall result from this interaction. Depending on the geometry and flow conditions, periodic boundary conditions can be implemented to reduce the computational effort. If fluid flow is negligible, simulations can be conducted without the need for solving Eqs. (3) and (4).

The modeling of the solid flow by DEM is at the individual particle level, while the gas flow by CFD is at the computational cell level. As shown in Fig. 2, their coupling is numerically achieved as follows. At each time step, DEM will give information, such as the positions and velocities of individual particles, for the evaluation of porosity and volumetric fluid drag force in a computational cell. CFD will then use these data to determine the gas flow field which then yields the fluid drag forces acting on individual particles. Incorporation of the resulting forces into DEM will produce information about the motion of individual particles for the next time step. The fluid drag force acting on individual particles will react on the fluid phase from the particles, so that Newton's third law of motion is satisfied (Xu and Yu, 1997; Zhu et al., 2007; Zhou et al., 2010).

Fig. 2 Coupling and information exchange between continuum and discrete models (Xu and Yu, 1997).

Model validity and application

Particle packing

Random packing of particles, as a core research area in particle science and technology, is fundamental to many operations in powder processing and is useful in modeling some physical systems. Its formation is a dynamic process involving various interparticle forces as discussed above. Therefore, a successful simulation method must take into account all dynamic factors related to both geometry and force. Most of the previous methods only consider the former and ignore the latter, and hence fail to generate realistic packing structures, particularly when forces rather than the gravity are dominant. DEM-based simulation offers a promising way to overcome this difficulty (Yang et al., 2000; Yu et al., 2006; Zhu et al., 2007; Tian et al., 2014).

Simulation conditions can vary to represent different packing processes, e.g., the spherical growth of a packing under a centripetal force like that used in isotropic compression or the vertical growth under gravity and other forces. Treatment such as vibration or compaction can also be implemented in a simulation. Here we only consider packing with vertical growth, which is typically conducted as follows. First, particles are randomly generated without overlap in a cylindrical or rectangular container. Then, the particles are allowed to settle down under the gravity and other forces. This dynamic process proceeds until all particles reach stable positions with an essentially zero velocity as a result of the damping effect for energy dissipation. This packing process is equivalent to a physical operation to transform a gas-fluidized bed to a fixed bed by stopping gas supply. Periodical boundary conditions can be applied to avoid the effect of side walls. Table 3 lists the parameters normally used to simulate the packing of glass beads. Note that Young's modulus is smaller than the real one in order to reduce the computational effort.

The validity of the simulation technique can be assessed at both macroscopic and microscopic levels. Fig. 3 shows the relationship between porosity and particle size for mono-sized spheres. The good agreement between the measured and simulated results confirms macroscopically the validity of the DEM and the important role of the van der Waals force in governing the behavior of fine spheres ranging from 1 to 100 μm (Yang et al., 2000). The split second peak in the radial distribution function has been recognized as a key feature for coarse spheres with negligible effect of the van der Waals force. For years, many investigators have struggled to reproduce this feature by computer simulation. As shown in Fig. 4, it can be readily generated with the present simulation technique. The results also show that radial distribution function varies with particle size or porosity. Coordination number is a more sensitive parameter in characterizing the packing structure. Fig. 5 shows the simulated coordination number distributions for a particle mixture are quantitatively comparable to those measured, confirming the validity of the DEM approach from the viewpoint of microstructure.

Table 3 Parameters for glass beads.

Parameter	Symbol	Base value
Particle density	ρ_p	$2.5 \times 10^3 \text{ kg m}^{-3}$
Young's modulus	Y	$1.0 \times 10^7 \text{ N m}^{-2}$
Poisson's ratio	$\bar{\sigma}$	0.29
Sliding friction coefficient	γ_s	0.3
Rolling friction coefficient	γ_r	0.005
Normal damping coefficient	η_i	$2 \times 10^{-5} \text{ s}^{-1}$
Hamaker constant	H	$6.5 \times 10^{-20} \text{ N m}$
Minimum separation	z_0	$1 \times 10^{-20} \text{ m}$

Fig. 3 Porosity vs particle size for glass beads: points, measured; line, simulated; and insets, packing structures taken from spherical samples for different sized spheres (Yang et al., 2000).

Fig. 4 The radial distribution function for packings of different sized particles, with the number showing the value of the first peak (Yang et al., 2000).

Fig. 5 Distribution of coordination numbers for the packing of a ternary mixtures of spheres (inset) when the size ratios are 4:2:1 and the volume fractions are 0.25, 0.50 and 0.25 for large (red), medium (purple) and small (green) components: o, measured contacts between medium and large components; x, measured contacts between medium and medium components; Δ , measured contacts between medium and small components; lines, simulated (Yi et al., 2011).

Fig. 6 Frequency probability distribution of normalized normal contact forces between particles for the packing of 1 mm spheres: +, simulated; —, measured (Yang et al., 2000).

Further comparison can be made in terms of interparticle forces. There is a good agreement between the simulated and measured distributions of normal contact forces between particles for a packing formed under gravity (Fig. 6). This demonstrates the capability of the DEM in generating quantitative force information which is difficult, if not impossible, to obtain with the current experimental technique.

The validated DEM model offers a convenient way to carry out controlled numerical experiments to study the packing of particles under various conditions. For example, it has been used to quantify the effects of material properties such as sliding and rolling friction coefficients related to the surface forces, Hamaker constant and particle density related to the body forces acting on a particle, as shown in Fig. 7. Correlations between macroscopic and microscopic or structural variables such as porosity, radial distribution function and coordination number can be established based on DEM simulations. An important finding from this type

Fig. 7 The effect of material properties on porosity ($\triangle$) and mean coordination number ($\square$): (a), sliding friction coefficient; (b), rolling friction coefficient; (c), Hamaker constant; and (d), particle density (Yang et al., 2000).

Fig. 8 The relationship between porosity and force ratio for glass beads, where $\chi_v = \frac{1}{N} |\sum_j \mathbf{F}_{v,ji} / m_i g|$ (Yang et al., 2000).

of studies is that macroscopic properties, e.g., porosity, can be described as a function of interparticle forces, i.e., the force ratio between the average van der Waals force and gravity force on a particle, as shown in Fig. 8. This relationship, as a state of equation, can be generalized in terms of cohesive force relative to effective gravity force, although further work is necessary to understand its dependence on variables related to surface forces.

Structural analysis is key to elucidating the packing mechanisms and the underlying physics. Realistic simulation of particle packing is crucial to such analysis. In fact, the resulting structural information can be directly used to study the structural properties of porous media, including, for example, permeability related to pore-to-pore connectivity and effective thermal conductivity related to particle-to-particle connectivity. DEM-based microstructural study will play a key role to quantify the governing mechanisms and generate reliable predictive methods for engineering application (Tian et al., 2014).

Particle flow in a horizontal rotating drum

Rotating drums are widely used in various industries for various purposes. A comprehensive understanding of the flow of particles in a drum under different conditions is essential for process control and optimization. It is also very much related to the physics of granular matter, e.g., particle avalanche in relation to heap formation or transition between fluid-like and solid-like modes. This example illustrates how such a process can be simulated and analyzed (Zhou et al., 1999; Zhu et al., 2007; Gan et al., 2020).

We have simulated the flow of glass beads in a horizontal drum of diameter 100 mm and thickness 16 mm (Yang et al., 2000). The drum is 35% filled with spheres of diameter 3 mm and rotates at various pre-set speeds. Periodic conditions apply axially to reduce the number of particles used; the analysis is for simplicity two-dimensional, achieved by averaging the data along the axial direction. Depending on the rotation speed, different flow regimes have been identified; but the cases considered here are in the so-called rolling regime that is commonly used in practice. The flow of particles in this regime has been well documented in the literature. Driven by the rotating drum, particles participate in collective solid rotation, reaching the filling surface inclined at an angle of repose from the rotating bulk at the bottom, pouring down this surface and getting mixed at the same time and then being re-trapped into the rotating bulk. This is indeed what is observed in the simulation, as shown in Fig. 9.

Fig. 9 Velocity fields in a plane section taken from DEM simulation (top) and PEPT experiment (bottom) at rotation speeds of: (a), 20 rpm; (b), 42 rpm; and (c), 65 rpm (Yang et al., 2003).

Fig. 10 Dynamic angle of repose as a function of rotation speed: $\diamond$, PEPT measurement; $\square$, DEM simulation (Yang et al., 2003).

Fig. 11 Angular velocity along the radius perpendicular to the flowing surface at rotation speeds of: $\square$, 20 rpm; $*$, 42 rpm; and $\triangle$, 65 rpm. Points are the PEPT measurements, and solid lines are the simulated results (Yang et al., 2003).

The validity of the simulation technique can be assessed by directly comparing the simulated and measured results. It is very useful to do so at a particle scale. One of the experimental techniques to produce such data is the so-called Positron Emission Particle Tracking (PEPT) (Zhou et al., 2004; Zhu et al., 2007). Fig. 10 shows the dependence of the dynamic angle of repose on rotation speed. The agreement between the DEM simulation and PEPT measurement is good, both indicating the angle increases linearly with the speed of rotation for the range considered.

Fig. 9 also shows the flow patterns produced by the DEM are comparable to those generated by PEPT at different rotation speeds. To be more quantitative, Fig. 11 plots the angular velocity along the radius perpendicular to the flowing surface, i.e., line $\overline{AB}$ AB in Fig. 9. Obviously, the agreement between the simulation and experiment is good. Satisfactory agreement between DEM and PEPT can also be observed for other processes such as bladed mixer and gas fluidization. It is noticed that the simulated velocity near the flow surface is higher than the PEPT velocity. This difference is mainly because the DEM simulation may not fully represent the PEPT experimental conditions, for example, the wall properties are simply assumed to be the same as those of particles in the DEM simulation. The selection of parameters for simulation is important to generate results matching physical experiment. The different sampling methods used in the simulation and experiment may also contribute to this observed discrepancy. Unlike the PEPT which determines the velocity field using the trajectory data of a single particle, the velocity field obtained from the DEM simulation is the average of the instantaneous velocities of all particles in the system.

The dynamics of particle flow includes at least three aspects: velocity, structure and force. Previous studies have to be largely limited to velocity field because of the difficulty in obtaining information for the other two. Consequently, there have been problems in probing the underlying mechanics and solving practical problems reliably. DEM is an effective technique that can overcome this problem. Its results can be readily used to establish the spatial and statistical distributions of important variables related to flow and force structures such as porosity, coordination number and various forces acting on particles. These variables can be treated as local average variables. As an example, Fig. 12 shows some typical results when the rotation speed is 42 rpm.

Fig. 12 Spatial distribution of: (a), porosity; (b), (snapshot) force network, total force (mg); (c), collision velocity (ms^{-1}); and (d), collision frequency (s^{-1}) when the rotation speed is 42 rpm (Yang et al., 2003).

Non-uniformity is obvious. For example, the bottom part, i.e., the rotating solid bed, has a lower porosity while the top part, i.e., flow layer, has a higher porosity (Fig. 12a). The normal contact force is important as other contact forces (e.g., tangential contact force) are directly related to it. Fig. 12b shows the force network in terms of this force, where each stick represents one connection between two particles with its thickness representing the magnitude of the force. As expected, large forces occur to particles at the bottom wall region to provide supports to the top particles. However, relatively large forces can also be found at the lower joint region between flow layer and rotating solid bed where particles of high velocity pouring down the bed surface impact the particles of low velocity waiting to start the bed rotation movement. Particles at the top have minimum contact forces. Notably, the force network actually also represents the flow structure of particles.

Understanding the interactions among particles is important for such a dynamic system (Zhou et al., 2004; Zhu et al., 2007). For example, the size enlargement or reduction process depends on two important factors: the effectiveness of a collision and the frequency of collisions between particles. The effectiveness is mainly related to the so-called initial kinetic energy or impact energy which is proportional to the square of the relative collision velocity between two particles v_{ij} ($=|\mathbf{v}_i - \mathbf{v}_j|$). Fig. 12c shows the spatial distribution of relative collision velocity. It demonstrates the most vigorous interaction between particles is at the lower joint point between flow layer and rotation solid bed. It then propagates into the bed mainly along the shear band between the flow layer and rotation solid bed. As shown in Fig. 12d, the spatial distribution of collision frequency has a similar pattern. A region of high relative collision velocity corresponds to a region of high collision frequency, or vice versa. Note that the concept of collision differs from that of contact between particles. The contact or coordination number is determined by “freezing” the bed. In contrast, particle collision is a dynamic process and a collision must be from two non-contacting particles. Fig. 12d is obtained when two particles come to contact from a gap of at least 1% of particle diameter.

Fig. 13 Schematic illustration of the effect of rotation speed on the growth kinetics of agglomerate size (Yang et al., 2003).

The resulting information can be used to understand the performance of industrial operations. We here take particle size enlargement by agglomeration as an example. Increasing rotation speed can increase the impact energy per collision and the collision frequency, giving two opposite effects on agglomeration in a drum. The increased kinetic energy will promote the breakage, crushing and abrasion of agglomerates, decreasing the growth rate. On the other hand, the increased collision frequency means more contacts or coalescences among particles within a given time period, leading to an increased growth rate. Consequently, as schematically shown in Fig. 13, depending on the rotation speed and operational conditions, various growth kinetics can result from the two opposite effects.

Gas fluidization of cohesive powders

It has long been recognized in practice that powders show four distinct behaviors, i.e., cohesive, aeratable, sand-like and spoutable, when fluidized. Theoretically, these behaviors must be related to particle-particle and particle-fluid interactions (Xu and Yu, 1997; Zhu et al., 2007; Zhou et al., 2009; Hou et al., 2012; Gan et al., 2016; Chen et al., 2012). Through controlled numerical experiments, the role of various interparticle forces can be examined. The simulations are carried out in a rectangular packed bed. Gas is then introduced uniformly at the bottom of the bed at a specified velocity to start a coupled gas-solid flow. Table 4 lists the physical parameters used in this work. Different from the above two examples, it is assumed that $\gamma_r = \sqrt{R_i^2 - (R_i - 0.5\delta_{ij})^2}/R_i$.

Fig. 14 summarizes the gas and solid flow patterns in the sequence of increasing gas velocity, with particles colored in a layered pattern according to their initial positions in the bed to demonstrate the particle rearrangement and mixing. Three states can be seen in this figure: fixed bed, expanded bed and fluidized bed. In the fixed bed, there is no observable structural change in the bed. Gas simply flows through interstices among stationary particles. In the expanded bed, cavities or large pores of different sizes and orientations are formed. Generally speaking, the cavities show an elongated shape and are predominantly horizontal. The expanded bed terminates at the so-called minimum bubbling velocity which is about 0.028 m/s from the simulation. In the fluidized bed, sustainable bubbles appear in the bed. The predicted trends are qualitatively in good agreement with those observed.

The analysis of the forces acting on individual particles is important to understand the phenomena observed. This can be demonstrated in the analysis of the origin of bed expansion. Fig. 15 shows the variation of the overall averaged contact force, the van der Waals force and fluid drag force relative to particle gravity during the transition from a fixed bed to an expanded bed when $u = 0.024$ m/s. Three stages, i.e., startup, transient and stable, can be identified in this figure. In the startup stage, both the contact and van der Waals forces increase sharply within a short time. The two forces reach their maximum and then the contact force fluctuates at this level while the van der Waals force decreases. In the transient stage, the fluctuation in contact force is attenuated and the van der Waals force starts to increase. In the stable stage, the contact force and van der Waals force balance each other. The fluid drag force is virtually maintained at a value just balancing the weight of the bed during all three stages, a fact that highlights the

Table 4 Parameters used for the present simulation.

Solid phase		Gas phase	
Particle shape	Spherical	Type of gas	Air
Number of particles, N	45,000	Viscosity, μ_f	$1.8 \times 10^{-5} \text{ kg m}^{-1} \text{ s}^{-1}$
Particle diameter, d	$1.0 \times 10^{-4} \text{ m}$	Density, ρ_f	1.205 kg m^{-3}
Particle density, ρ_p	1440 kg m^{-3}	Bed width	$2.5 \times 10^{-2} \text{ m}$
Spring constant, κ	50 Nm^{-1}	Bed height	$4.5 \times 10^{-2} \text{ m}$
Sliding friction coefficient, γ_s	0.3	Bed thickness	$1.0 \times 10^{-4} \text{ m}$
Contact damping coefficient, η	$1.65 \times 10^{-5} \text{ kgs}^{-1}$	Cell width	$1.0 \times 10^{-3} \text{ m}$
Hamaker constant, H	$2.10 \times 10^{-20} \text{ Nm}$	Cell height	$1.0 \times 10^{-3} \text{ m}$

Fig. 14 Particle configurations and gas flow fields for different superficial gas velocities, showing the existence of fixed ($u = 0.0 \text{ ms}^{-1}$), expanded ($u = 0.024 \text{ ms}^{-1}$) and fluidized beds ($u \geq 0.028 \text{ ms}^{-1}$) (Yu and Xu, 2003).

Fig. 15 Variation of dimensionless ensemble-averaged contact force, van der Waals force and fluid drag force with time when $u = 0.024 \text{ ms}^{-1}$.

rapid response from the solid phase, by changing its porosity, to the fluid drag force induced by gas flow. Clearly, the contact force must be balanced by the van der Waals force to form a stable expanded bed. Further analysis of the spatial distributions of the two forces indicates that the balance between them is observed not only at a bulk average scale but also at an individual particle scale, as shown in Fig. 16. If the van der Waals force is unable to balance the contact force after initial disruption of the fixed bed, instability and then fluidization result.

Fig. 16 Spatial distribution of the magnitudes of: (a), contact force; (b), van der Waals force acting on individual particles in an expanded bed when $u = 0.024 \text{ ms}^{-1}$. The forces relative to the gravity of a particle are shown in a logarithm scale (Yu and Xu, 2003).

Fig. 17 shows the sequences of gas-solid flow patterns when increasing magnitude of the van der Waals force, where the change of the van der Waals force is achieved by adjusting the Hamaker constant. Three regimes of fluidization can be identified from this figure: good fluidization, quasi-fluidization and defluidization. When the ratio of the maximum van der Waals force (determined when $z = z_0$) to particle gravity is less than about 30, good fluidization is obtained with continuous bubbles of relatively small sizes rising through the bed. When the force ratio is in the range of about 40 to 100, the fluidization quality deteriorates significantly and severe channeling occurs although the bed is still fluidizable at higher gas velocities. When the force ratio is greater than about 300, the fluidization is impossible by normal means. The simulation well reproduces the phenomena experimentally observed, leading to the quantification of the roles of various particle-particle and particle-fluid interaction forces for this gas-solid flow system (Hou et al., 2012). This approach has been extended to more complicated particle-fluid flow systems including, for example, heat and mass transfer coupled with chemical reactions, and non-spherical particles such as ellipsoids (Gan et al., 2016; Zhou et al., 2011; Kuang et al., 2018, 2020).

Fig. 17 Gas-solid flow patterns when the ratio of superficial gas velocity to minimum fluidization velocity is 4.8 and the ratio of van der Waals force to particle weight is (a) 10, (b) 70, and (c) 300. The particles are colored according to their initial heights in the bed to visualize the solid mixing (Yu and Xu, 2003).

Conclusion

The bulk behavior of granular materials depends on the collective interactions among individual particles. Particle scale modeling and analysis are therefore key to elucidating the underlying physics and linking fundamental to applied research, particularly in developing from know-how to know-why knowledge. The examples discussed in this article clearly demonstrate that discrete particle simulation, although not perfect at this stage of development, does capture the main features and is an effective way to achieve this goal. With the rapid development of computer technology, it offers a cost-effective way to meet the challenge of understanding the ever-changing particle science and technology resulting from the continuing development of new processes and products. Indeed, we have seen this development in the past two decades or so, leading to various breakthroughs or new developments in simulation and modeling of particulate systems. For example, facilitated with suitable constitutive relations, granular flows in different flow regimes can be simulated now (Zheng and Yu, 2017; Zheng et al., 2019).

Abstract

Clusters are ultrasmall particles with about 1 nm size composed of a dozen atoms and show peculiar catalytic, optical, and magnetic activities. In contrast to bulks and nanoparticles, adding or eliminating only a single atom drastically changes a cluster's properties due to its amorphous structure and quantum size effects. Interestingly, some clusters called superatoms have atom-mimic electronic configurations and characteristics; thus, the periodic table of clusters has been proposed. Recent developments allow us to obtain clusters in the gas, liquid, and solid phases and use them as materials. Clusters will be new building blocks in future science.

Key points

- Recent developments allow obtaining clusters in the gas, liquid, and solid phases.
- The addition or elimination of only a single atom drastically changes a cluster's properties.
- Clusters called superatoms have atom-mimic properties and could be new building blocks.

Introduction

In materials science, bulk materials, including crystal and amorphous ones, have a long history. Metal, semiconducting, and dielectric bulks provide a foundation for most modern technology. After the 1990s, nanoparticles received much attention as a novel material instead of the bulks. Nanoparticles are much smaller particles than the bulks, whose size is only ~ 10 nm or $\sim 10^2$ nm. They exhibit extraordinary optical, magnetic, and catalytic properties due to their small size and high surface area; therefore, they are being put to industrial use. Recently, there has appeared the third material, i.e., sub-nano particles. Sub-nano means a particle size of about 1 nm (Fig. 1). Such ultrasmall particles contain only a dozen atoms. Because of the difficulty in precisely synthesizing them, they have not been considered materials. However, recent experimental developments enable us to obtain them in the liquid and solid phases, thereby telling us that they differ entirely from the bulk and nano ones.

Sub-nano particles have unexpectedly been known for a long time. After the 1980s, in the fields of molecular physics and physical chemistry, they have been called clusters. A carbon material shaped like a soccer ball, i.e., fullerene, which is composed of 60 carbon atoms, is a typical example of a cluster (Kroto et al., 1985). Synthesizing clusters is quite simple. Suppose one irradiates an intense laser beam onto a bulk metal in a vacuum. Metal atoms and molecules with high energies evaporate from the surface. Such metal gases spontaneously aggregate to form polyatomic particles called clusters. They can be ionized and mass-separated under an electric field. Many clusters with various sizes have thus been synthesized and analyzed. However, this method faces a problem; the amount obtained at one time is very low on most picogram scales. Clusters are, therefore, difficult to be utilized as materials.

Recently, there appeared breakthroughs in the synthesis methods for clusters. The chemical reduction methods for nanoparticles (Cushing et al., 2004) help synthesize clusters. In a solution, a reducing agent converts metal salts into bare metal atoms, which aggregate into larger particles. To avoid the undesirable formation of bulks or nanoparticles, some sophisticated techniques are needed; i.e., polymer protection (Tsunoyama et al., 2004, 2008; Tsunoyama and Tsukuda, 2009), ligand protection (Bartlett et al., 1978; Zhang et al., 2004; Schmid et al., 1981; Brust et al., 1994), etching (Shichibu et al., 2007), or dendrimer-templated synthesis

Fig. 1 Structural hierarchy in materials science.

(Zhao et al. (1998); Satoh et al., 2008; Yamamoto et al., 2009), as described later in detail. At the same time, size-separation techniques and conversions to the solid states are also being developed. These techniques enable us to obtain a cluster with a specific number of its constitutive atoms in the liquid and solid phases. With the help of these sophisticated methods, clusters can be used as materials.

With developing synthetic methods, many scientists have also studied applications of clusters (Liu and Corma, 2018). Since the discovery of the unexpected catalytic activity of nanoparticles by Haruta et al. (1987), it is well known that the nanoparticles' properties differ entirely from the bulks. Afterward, the difference between nanoparticles and clusters received much attention. Various properties of nanoparticles change smoothly as their size varies. For instance, the catalytic activity smoothly increases as the particle size decreases because the total surface area becomes more extensive. However, in the size range of clusters, the dependence of the catalytic activity on the size is zigzag (Imaoka et al., 2015), as shown in Fig. 1. Thus, their properties depend not on the diameter of the clusters but on the number of constitutive atoms. The bulk and nanoparticle favor close-packed structures in many cases, but clusters are intrinsically amorphous. For clusters, crystalline structures are unstable due to their large surface areas. As clusters become larger, i.e., with more than dozens of constitutive atoms, crystalline-like forms occasionally appear from the inside. The addition or elimination of only an atom, hence, drastically affects catalytic activity. This is a uniqueness of clusters. In other words, a cluster is considered an individual molecule that has long been challenging to find.

Remarkably, clusters offer a new science of superatoms instead the conventional science based on the elements. The superatom, meaning a specially stable cluster, is a novel, higher-order concept than an atom. It has electronic orbitals and an electronic configuration like an atom. Quantum mechanics can validate such an idea. For instance, a typical superatom, the Al_{13} cluster, resembles a chlorine atom (Bergeron et al., 2004). Due to its atom-mimic electronic configuration, a superatom has a chemical property like an atom and can be used as a building block for larger compounds. This is a modern kind of alchemy. Recent studies have shown that there could be a periodic table of clusters analogous to the periodic table of the elements (Tomalia and Khanna, 2016; Tsukamoto et al., 2019). While modern physics and chemistry are based on the elements, clusters could provide a foundation for future science.

In this article, we give the readers the theoretical and experimental essences of clusters. First, we look at the shell model describing the electronic states of clusters and explain their stability. In this context, we introduce the novel concept of the superatom and also the periodic table of clusters. We then review the experimental developments; i.e., various synthetic methods, separation techniques, characterizations, and applications. The reader can now overview the overall picture of clusters and their future perspectives.

Theoretical principles

In sub-nano science, the theoretical concept of superatoms appeared. First, let us look back on the conventional atom. This can be seen in an elementary quantum mechanics textbook, but it is essential and suggestive for considering the analogy of clusters and atoms. An atom is a positively charged massive nucleus surrounded by a cloud of negatively charged light electrons. The electronic states determine the materials' properties; i.e., stability, appearance, conductivity, magnetism, etc. Each one-electron state is called an orbital, especially an atomic orbital in this case. The orbital comes from the orbit, which is the traveling path of an astronomical object. Depending on the angular momenta, the shapes of the atomic orbitals are classified as s, p, d, f, ...; e.g., an s atomic orbital has a spherical shape, and p atomic orbitals have three dipolar shapes in the x, y, and z-directions. Different orbitals with the same energy are termed to be degenerate. The degrees of degeneracies are 1, 3, 5, 7, ... for the s, p, d, f, ... orbitals, respectively.

In general, different types of orbitals have different energy levels. The constitutive electrons of the atom occupy their atomic orbitals to minimize its total electronic energy based on the Pauli exclusion principle and Hund's rules. The former originates from the spin-statistics theorem and forbids the occupation of the same single orbital by more than two electrons. The latter comes from the potential exchange interaction and arranges the spins, which are magnetic dipoles intrinsic to electrons, as ferromagnetic as possible in the degenerate orbitals. For instance, a hydrogen atom has an electron partially occupying the 1s atomic orbital; a carbon atom has six electrons fully occupying the 1s and 2s atomic orbitals and partially occupying the 2p orbitals. Note that the 1s and 2s atomic orbitals are both s atomic orbitals, but their shapes in the radial direction are slightly different. How electrons occupy orbitals in an atom is called its electronic configuration, which is intrinsic to each atom.

Clusters also have electronic orbitals. A cluster is a molecule with multiple nuclei surrounded by electronic clouds composed of molecular orbitals. Interestingly, the molecular orbitals of clusters, especially highly-symmetrical clusters, have shapes just like the atomic orbitals. They are thus called superatomic orbitals (Fig. 2). Of course, superatomic orbitals are not localized at a single atom but delocalized over the cluster. A molecular orbital resembling an s atomic orbital is called an S superatomic orbital. This analogy can be understood based on the shell model (de Heer, 1993). The shell model originates from the electronic structure of an atom. Interestingly, it can also be used to describe the structure of an atomic nucleus in the field of nuclear physics. The shell model regards a cluster as the three-dimensional spherical potential with valence electrons and entirely ignores its detailed molecular structure. A potential that is easy to be analyzed is employed. For instance, the jellium model (the infinite/finite potential well), the harmonic potential, or their intermediates such as the Woods–Saxon potential. In any case, it is assumed that a cluster is spherical. This approximation is valid only for highly-symmetrical metal clusters. The electronic Schrödinger equation for this model can be solved and electronic orbitals can be obtained with their energy levels. The product of radial and spherical harmonic functions gives each superatomic orbital in the same manner as atomic orbitals.

As with atomic orbitals, the full occupation of superatomic orbitals by electrons is expected to result in stable closed shells. Recall the electronic configurations of noble gases. On the other hand, Hund's rules suggest that the arrangement of electronic spins in the degenerate orbitals could be ferromagnetic, leading to a high magnetism. Thus, in the case of clusters, their molecular properties can be understood and predicted in analogy to atoms. Furthermore, it is expected that there exists a cluster with nearly the same electronic configuration as an atom. The number of valence electrons necessary for the stable closed shell is termed the magic number. Here, core electrons are ignored. This simplification is valid since the core and valence orbitals can be separable in many cases. Many clusters satisfying the magic number requirement have been detected and characterized by gas-phase spectroscopic methods. A cluster with the atom-mimic electronic configuration is called a superatom. The same electronic configuration implies the analogy of various chemical properties. The most outstanding example is the aluminum cluster, Al_{13} , having an icosahedral symmetry. Indeed, Bergeron et al. (2004) reported that Al_{13} shows a chemical behavior resembling a halogen. Al_{13} had been synthesized on a picogram scale in the gas phase for fundamental research. Still, Kambe et al. (2017) succeeded in its synthesis on a large scale in the liquid phase. The molecular orbitals of this cluster are S, P, ... superatomic orbitals, and a stable closed-shell structure is formed similar to that of a chlorine anion. Other examples have also been reported, including Au_{20} with a tetrahedral symmetry (Li et al., 2003).

Physicists and chemists have assembled various compounds using atoms, but from now on, they could use superatoms as building blocks for larger compounds. Qian et al. (2010) obtained a dimer of gold superatoms, which can be regarded as a higher-order molecule. Roy et al. (2013) obtained cocrystals of superatoms and fullerenes. The emergence of superatoms thus implies a new era of materials science. In 1869, Mendeleev proposed the periodic table of the elements. It has long been the foundation of the natural sciences and contributed to discovering many elements that obey the periodic rule. Thereafter, higher-order substances, including molecules, clusters, nanoparticles, and bulks, have received much attention. However, it still remains challenging to predict and design such higher-order substances. As with Mendeleev's periodic table, such a periodic table for higher-order substances would be valuable. Tomalia and Khanna (2016) pointed out the possibility of nano-periodicity in higher-order substances typified by superatoms.

Fig. 2 The shell model and superatomic orbitals.

Fig. 3 The splitting of superatomic orbitals in actual shapes of clusters.

As described earlier, clusters have often been predicted based on the shell model which assumes that their structures have an approximately spherical symmetry. However, this spherical approximation is applicable especially for subglobular clusters like icosahedrons (Fig. 3). Indeed, the initially discovered superatom was the Al_{13} cluster with an icosahedral symmetry. A theoretical framework that describes a broader range of clusters is necessary to obtain a universal law. Though the shell model is a candidate for such a theory, most clusters are not quasi-spherical because the numbers of their constitutive atoms are inappropriate for constructing highly-symmetrical structures like icosahedrons. Even if they have icosahedral atomicities, many clusters exhibit a Jahn–Teller or pseudo-Jahn–Teller instability due to electronic reasons. The former states that the partial occupation of degenerate orbitals by electrons gives rise to spontaneous symmetry-breaking of the clusters' structures. The latter states that the pseudo-degeneracy, or near miss of energy, between occupied and unoccupied orbitals causes spontaneous symmetry-breaking of the clusters' structures.

Notice that exceptionally stable clusters with lower symmetries than icosahedrons have also been found, such as Au_{20} with a tetrahedral symmetry (Li et al., 2003). In such clusters, the validity of the shell model relatively decreases due to the split and shift of the superatomic orbital levels, implying that it is desirable to establish a more sophisticated method to find an abundance of stable clusters. To broaden the scope of the shell model, Tsukamoto et al. (2019) proposed the symmetry-adapted orbital model, which explicitly takes into account the level splittings of the electronic orbitals due to lower structural symmetries, as well as the number of valence electrons and the number of constitutive atoms. This model tells us there are different magic numbers for different cluster shapes. This refinement implies the possibility of an abundance of stable clusters with various shapes that obey a certain periodicity. The periodicity originates from the analogy of electronic configurations between superatoms and atoms. Consequently, all clusters with the same symmetry can be unified into a periodic framework analogous to the periodic table of the elements.

Syntheses and characterizations

In this section, we describe the experimental aspects. As stated in the Introduction, the cluster study starts in the gas phase. We here look at how to produce clusters in a laboratory. Laser ablation (Maruyama et al., 1990) and magnetron sputtering techniques (Xirouchaki and Palmer, 2004) are available. An intense laser or argon ion beam is irradiated onto a bulk metal in a vacuum. Metal atoms and molecules with high energies evaporate from the bulk surface. In the case of metals with low boiling points, heating can also cause evaporation (Baker et al., 2000). The vacuum chamber enables us to ignore collisions with background gases. Such metal gases spontaneously aggregate into clusters. However, various sizes of clusters are mixed at that time. For mass separation, the clusters should be ionized. Some ionization techniques have been developed; i.e., electron ionization (EI) (Jackschath et al., 1992) and photoionization (PI) (Letokhov, 1987). After ionization, applying an electric field accelerates ions, mass-separated clusters can be obtained by time-of-flight mass spectrometry (TOF-MS) or using a quadrupole mass analyzer (QMS) (Knight et al., 1986; Martin et al., 1991; Katakuse et al., 1985; Kim et al., 1994).

Mass separation can thus determine each cluster's mass, but its structure is yet unknown. The following techniques can estimate the structures of the clusters. One method is ultraviolet photoelectron spectroscopy (UPS) (Li et al., 2003; Lechtken et al., 2007; Huang et al., 2008, 2009; Häkkinen et al., 2003, 2004), which irradiates ultraviolet light into a cluster and detects the kinetic energy of the accompanying photoelectron. The energy difference between the incident light and photoelectron is the binding energy of the corresponding electron. The obtained spectrum reflects the density of states near the Fermi energy intrinsic to the cluster's structure. The structure reproducing the obtained spectrum can be found with the help of the first principles calculations. Photodissociation (PD) spectroscopy can also be used to estimate the structures of the clusters (Gilb et al., 2004). In this method, light is irradiated

onto a cluster, and then its dissociated fragments, including atoms, are detected. If a cluster cannot be photo dissociated, one can use a messenger like a noble gas that is attached to the target cluster and dissociated after photoirradiation. The obtained spectrum can nearly be regarded as the photoabsorption spectrum intrinsic to the cluster's structure. As with photoelectron spectroscopy, comparison with theoretical calculations clarifies the cluster's structure. Also, gas chromatography (GC) is a vital tool for estimating a cluster's structure (Dugourd et al., 1997; Gilb et al., 2002). Under an electric field in a gas, the cluster moves along with a collision with gaseous atoms and molecules. The obtained ion mobility is related to the cluster's cross-section, reflecting its geometrical structure. Electron diffraction in an ion trap (TIED) can also be employed (Schooss et al., 2010; Xing et al., 2006). Comparing the diffraction patterns between experiments and calculations estimates the cluster's structure.

Recently, clusters in the gas phase can be captured onto solid surfaces. This capture is vital for characterization and applications because available analyses for gaseous clusters are limited. One method is to utilize the defects of metal oxide surfaces, which effectively form chemical bonds with clusters (Sanchez et al., 1999). In general, however, clusters fly rapidly ($\sim$ keV) in the gas phase. The collision of clusters with solid surfaces destroys the clusters, violating the merit of in-advance mass separation. The clusters must be slow down before adsorption. For that purpose, Mitsui et al. (2006) introduced self-assembled monolayers on the surface as impact absorbers (soft-landing isolations).

We subsequently look at the syntheses in the liquid phase. Success in the liquid phase required more years of research than in the gas phase. The reason is the inevitable instability of clusters due to their high surface areas per molar amount, amorphous structures, and quantum size effects. In the conventional chemical reduction methods for nanoparticles (Cushing et al., 2004), metal salts are dissolved in a solution and a reducing agent is used, thus converting metal salts into bare metal atoms. The bare metal atoms quickly aggregate to form particles larger than clusters. The undesirable formation of bulks or nanoparticles must be avoided. For that purpose, various protection methods have been developed. One method uses polymers, including polyvinylpyrrolidone (PVP) (Tsunoyama et al., 2004, 2008; Tsunoyama and Tsukuda, 2009). For instance, gold clusters surrounded by a polymer can be separated in a solution. Another protection method is ligand protection. Organic ligands, including phosphine (Bartlett et al., 1978; Zhang et al., 2004; Schmid et al., 1981) and thiolate (Brust et al., 1994), can be introduced onto a cluster's surface. Some ligand-protected clusters can be crystallized.

Along with the ligand-protection method, an etching technique has also been developed (Shichibu et al., 2007). While mixing metal salts and reducing agents, an excessive amount of ligands are added to the solution. First, large clusters are formed and coordinated by some ligands. The clusters subsequently become smaller etched by ligands. Finally, only specific stable clusters with the magic number remain. Ligand protection methods can also synthesize Zintl ions; i.e., anionic clusters consisting of an alkali or alkaline earth metal and a post-transition metal or metalloid (Wilson et al., 2018). They are named after E. Zintl and have a more extended history than many other cluster compounds.

Liquid-phase syntheses are in the same situation as gas-phase syntheses. Since a mixture of clusters with various sizes is obtained when synthesized, size separation is indispensable. Size-exclusion chromatography (SEC) is a typical technique that transports clusters through the column packed with fine, porous beads (Murayama et al., 2004; Tsunoyama et al., 2007). The time for transporting depends on the clusters' sizes. Polyacrylamide gel electrophoresis (PAGE) is also used for size separation, in which cluster ions move in a gel under an electric field (Negishi et al., 2005; Tsunoyama et al., 2006). The measured electrophoretic mobility depends on the clusters' sizes and charges. Electrospray ionization mass spectrometry (ESI-MS) can be used for the same purpose (Negishi et al., 2005; Chaki et al., 2008). Applying an electric field allows a solution including clusters to be tiny charged droplets, then time-of-flight mass spectrometry enables us to separate them. Similarly, the matrix-assisted laser desorption/ionization (MALDI) technique embeds clusters into a laser-absorbing matrix and photoionizes the matrix (Tsunoyama et al., 2010).

In the ligand protection method, a single crystal of a cluster can be occasionally obtained. This is a fortunate case. If so, the single-crystal X-ray diffraction (SC-XRD) measurement gives direct information about the structure of a cluster (Heaven et al., 2008; Qian et al., 2010; Jadzinsky et al., 2007). If not, various techniques are usually combined to estimate the structure of a cluster. X-ray photoelectron spectroscopy (XPS) tells us the oxidation states of the constitutive atoms of the cluster (Inomata et al., 2018). It irradiates X-ray into a cluster and detects the kinetic energy of the accompanying photoelectron. The energy difference between the incident X-ray and photoelectron is the binding energy of the corresponding core electron, which is intrinsic to the atom's oxidation state. For a negatively-charged atom, the binding energy is lower. In contrast, the binding energy is higher for a positively-charged atom. The oxidation states of the constitutive atoms of the cluster can be determined by comparing them to the reference bulk samples whose atoms' oxidation states are already known. The extended X-ray absorption fine structures (EXAFS) analysis, which observes the scattering of photoelectrons by the adjacent atoms, estimates the coordination number around each constitutive atom (Yamazoe and Tsukuda, 2019). The high-resolution scanning transmission electron microscopy (HR-STEM) has been dramatically improved, and the number of its constitutive atoms can be visually counted (Imaoka et al., 2017). Energy-dispersive X-ray spectroscopy (EDS), though its resolution is not so high, tells us the elemental components of a cluster (Tsukamoto et al., 2018). This technique is essential for poly-elemental clusters.

Recently, there appeared a breakthrough in liquid-phase syntheses. This new method also utilizes the typical synthetic method for nanoparticles; i.e., the chemical reduction method (Cushing et al., 2004). The problem was that the obtained particles rapidly grow larger than the nanoscale ones. Zhao et al. (1998) proposed one idea to overcome this difficulty; they confined metal salts and reducing agents into small reaction fields in a solution. A typical reaction field is a dendrimer, a new type of polymer with many branches and specific molecular weight. If adsorption sites for metal salts are embedded into the dendrimer in advance, a certain amount of metal salts can be accumulated in a single dendrimer. By adding reducing agents, the metal salts form a cluster inside the dendrimer. Branches of the dendrimer prohibit the unfavorable aggregation of clusters.

Furthermore, Yamamoto et al. (2002) introduced a specially fine-tuned dendrimer, the phenylazomethine dendrimer (DPA), in which metal salts stepwise adsorb on its imine sites from the inner layers to the outer layers. Remarkably, the number of metal salts coordinated onto this dendrimer can be spectroscopically observed as the change in the isosbestic points. In this case, size separation of the clusters is unnecessary because the number of the constitutive atoms of a cluster is controlled at nearly one-atom precision when synthesized (Satoh et al., 2008; Yamamoto et al., 2009). With this sophisticated dendrimer-templated method, many clusters were successfully synthesized in a liquid (Kambe et al., 2017; Tsukamoto et al., 2018). Besides, the accumulation of different metal salts into the dendrimer even enables us to synthesize poly-elemental alloy clusters. Supporting the obtained clusters on substrates avoids aggregation and leads to various analyses and applications.

Applications

In the late 1980s, Haruta et al. (1987) showed that if inert gold bulk is made to be in a nanoscale, it provides a catalytic activity. This discovery is the beginning of nanoscience, and many physicists and chemists have studied nanoparticles. A typical example of a smaller particle than the bulks is a nanoparticle, while its extreme example is a cluster. One can easily imagine that clusters possess exceptional potential, including a catalytic activity. They have high surface areas, amorphous structures, and nontrivial quantum size effects. Indeed, many researchers reported their higher catalytic activity than the bulks and nanoparticles (Liu and Corma, 2018). That is, however, not all.

Imaoka et al. (2013) elucidated that the oxygen reduction catalytic activity discretely depends on the cluster's atomicity. The Pt₁₂ and Pt₁₃ clusters showed completely different catalytic activities. The oxygen reduction reaction was significantly enhanced when only one atom was removed from Pt₁₃. It was considered due to the contrast between the deformed coordination of Pt₁₂ and the icosahedral coordination of Pt₁₃. In the sub-nano region, the addition or elimination of one atom drastically changes the catalytic activity. This discrete property is entirely different from the properties of the bulk and nano. Since the bulk and nano have many constitutive atoms, adding or eliminating one atom is not essential. In this context, each cluster can be considered an individual molecule with unique properties. Besides, poly-elemental clusters have more potential applications, including catalysis. Takahashi et al. (2017) reported that multimetallic clusters composed of copper, platinum, and gold with a specific composition ratio exhibit 24-times greater activity than that of a commercially available Pt catalyst for the aerobic oxidation of hydrocarbons. Such atom hybridization adds a new dimension to clusters (Tsukamoto et al., 2018).

In the case of ligand-protected clusters, there is the possibility that ligands prohibit catalytic reactions. This concern is natural because ligands are introduced to enhance the stability of clusters, in other words, to make them inert. However, some reports showed that ligand-protected clusters are still catalytically active. Thiolate-protected gold clusters, including Au₂₅(SR)₁₈ supported by titania or ceria, enhance selective hydrogenations (Zhu et al., 2010a), styrene's epoxidation (Zhu et al., 2010b), and carbon monoxide oxidation (Nie et al., 2012). These results are surprising because they are contrary to common sense that the catalytic activity of gold is lost by sulfur poisoning.

Grandjean et al. (2018) observed the bright luminescence of the hydrated Ag₄ cluster in zeolites. This luminescence is assigned to the electronic transition between superatomic orbitals. Some gold clusters with ligands including alkynyl (Wan et al., 2015) and N-heterocyclic carbenes (Narouz et al., 2019) also show a good luminescence. Fine-tuning the atomicity of clusters and the types of ligands could broaden the applications of clusters. The intense luminescence of gold clusters can also be observed when coordinated by dendrimers (Zheng et al., 2003, 2004), proteins (Xie et al., 2009), and tetraoctylammonium cations (Pyo et al., 2015). Wang et al. (2014) reported that doping silver atoms into gold clusters considerably enhances the luminescence of the gold clusters.

Using circular dichroism (CD) spectroscopy, which observes the absorption difference between left and right circularly polarized lights, the Cotton effect was observed for gold clusters protected by chiral ligands, including BINAP (Yanagimoto et al., 2006). The Cotton effect is the rapid change of circular dichroism in the absorption region and was named after A. Cotton. The observation of the Cotton effect implies that chiral information of the ligand is transferred into the cluster core. Furthermore, with the X-ray magnetic circular dichroism (XMCD), which observes the absorption difference between left and right circularly polarized X-rays under an external magnetic field, Negishi et al. (2006) investigated the magnetic moments of gold clusters protected by glutathione. They found that bonding at the gold/glutathione causes spin polarization of the gold clusters. The interaction of cluster cores and ligands is not totally clear, and its understanding and control could further broaden the potential use of clusters.

Recently, the cocrystallization of clusters with fullerene as well as the cocrystallization of different types of clusters were achieved (Roy et al., 2013; Pinkard et al., 2018; Doud et al., 2020). The success of synthesizing such new solid-state materials, called superatomic crystals, realized the emergence of novel collective properties; i.e. good electronic transport, thermal conductivity, and a magnetically ordered phase.

Conclusion

This article reviewed the history of a cluster, an ultrasmall particle on a sub-nano scale consisting of a dozen atoms. Its peculiar catalytic, optical, and magnetic characteristics are due to a high surface area, an amorphous structure, and quantum size effects. In the early stage, it could be synthesized only in the gas phase and could not be a material. Nowadays, it is the third material, an alternative to bulk and nano ones, due to the development of their liquid-phase syntheses and crystallization techniques.

Interestingly, some clusters have atom-mimic electronic configurations and chemical properties. Thus, they are called superatoms. The superatom is a higher-order concept than an atom. As with the conventional periodic table of the elements, a periodic table of superatoms has been proposed. Some superatoms have been synthesized in the liquid phase, and their cocrystals have also been obtained. Superatoms will be new building blocks in future science. Shortly, scientists could spread applications, including superatom-based devices, around the world.

Abstract

This chapter explores the remarkably varied electronic behavior of pure carbon species, including fullerenes and fullerite, graphene and graphite, nanotubes, diamond, amorphous carbons, and miscellaneous synthetic carbons such as nanorings and graphyne. We show how their diverse electronic structure derives directly from the different hybridizations possible between the 2s and 2p Carbon orbitals, the capability in Carbon for strong π bonding between 2p orbitals of neighboring atoms, and the dimensionality and symmetry of the resultant carbon forms. We discuss the diverse consequences of this electronic structure including ultra-hardness, negative electron affinity and superconductivity, and how the electronic states of carbon materials can be controlled through doping.

Key points

This chapter introduces key concepts of Carbon electronic structure and demonstrates how these underpin the wide variety of carbon forms and their unique individual behavior.

- *Underlying electronic structure*: Carbon has the possibility to hybridize into sp , sp^2 , and sp^3 configurations. When coupled with strongly overlapping p_z -orbitals creating π -bonds, this allows carbon atoms to form single, double and triple bonds with their neighbors.
- *Symmetry and dimensionality*: Depending on the atomic arrangements, carbon can form 0D molecules (fullerenes), 1D nanotubes, 2D graphene, and 3D structures such as graphite and diamond. Each shows distinct electronic properties resulting from the structural symmetry and dimensionality.
- *Materials Behavior*: We will draw on a range of practical examples, showing how the underlying electronic structure results directly in measureable material properties in carbon materials (such as transparency, superconductivity, hardness, and color).
- *Modifying Properties*: We will describe how the electronic structure of carbon materials can be modified and tuned, through doping, intercalation, and external stimuli such as electric fields and pressure.
- *Latest Advances*: We will highlight some of the latest discoveries and newest advances, including recently synthesized carbon materials such as carbyne nanorings and graphyne.

Introduction

Carbon is a remarkable element that shows a variety of stable and metastable structures, ranging from three-dimensional (3D) diamond via 2D graphene and 1D carbyne to 0D fullerenes. The different forms of carbon are the consequence of two important characteristics of its electronic $1s^2 2s^2 2p^2$ configuration. First, carbon may form different hybridizations, called sp^n , between its

[☆]*Change History*: April 2023. S. Latil and C. Ewels rewritten abstract, added objectives, updated text, added Miscellaneous Synthetic Carbons section, added new conclusion and summary, updated Table 1, Figures 4, 9, and added new Figures 5, 6, 7, 8, 9a, 10.

Table 1 Structural and electronic properties of the 3D carbon allotropes at room temperature.

2s orbital and n of its 2p orbitals ($1 \leq n \leq 3$). Next, the C–C distance is small enough to allow for a large π bonding between 2p orbitals of neighboring atoms that are not hybridized with the 2s orbital (when $n < 3$). These two properties together give wide structural flexibility, thanks to which the chemistry of carbon is so rich.

Already with pure carbon, different structures exist which have very different electronic properties. The three three-dimensional allotropic crystalline forms of carbon are listed in Table 1. Beyond these, the hexagonal symmetry of a graphite monolayer, graphene, results in unique charge carrier behavior as described below. Other more exotic structures are covered briefly later.

Hybrid orbitals

A carbon atom has six electrons. The two electrons in the 1s shell are energetically stable and never participate in chemical bonds or electronic response. The remaining four electrons should organize like [He](2s²)(2p²), leading to an atomic triplet state ³P₀, with two electrons embedded in a stable 2s orbital and only two valence electrons that can interact with neighboring species. However, the quintuplet state ⁵S₂ coming from the [He](2s¹)(2p³) configuration is less than 4 eV higher in energy, and explains why carbon can mobilize four electrons in chemical bonds. The way these four electrons are organized around the nucleus is the hybridization.

When two carbon atoms are brought together to form a C₂ molecule, the electrons move in an effective potential that has cylindrical symmetry around the line joining the two nuclei. A molecular wave function may be totally invariant under a rotation by an angle ϕ about this axis, thus forming a σ state, or it may transform like $\cos(m\phi)$, thus forming a π state ($m = 1$), a δ state ($m = 2$), etc. The ground state of the C₂ molecule is a σ state. Its expression can be written as a linear combination of atomic orbitals (LCAO) restricted to the 2s and 2p_z valence orbitals, which have full rotational symmetry about the molecular axis chosen as the z direction. In addition, the wave function of the ground state is even with respect to the inversion about the molecule center. This means $\psi_{\sigma_g} = (\Phi_{A+} + \Phi_{B-})/\sqrt{2}$, where $\Phi_{A+} = \alpha\phi_{As} + \beta\phi_{Az}$ and $\Phi_{B-} = \alpha\phi_{Bs} - \beta\phi_{Bz}$. In that expression, ϕ_{As} and ϕ_{Az} are the 2s and 2p_z orbitals located on one carbon atom, either at location A or B. Φ_{A+} and Φ_{B-} are linear combinations of these orbitals, called sp^1 hybrids (see Fig. 1a). They are symmetric to each other with respect to the inversion center. The numerical coefficients α and β are determined by solving a secular LCAO equation.

In a C₂ molecule, two electrons occupy the σ_g ground state (see Fig. 1b) and form a strong σ bond. Two electrons occupy the next σ state, which is a nonbonding state with wavefunction $\psi_{\sigma_u} = (\Phi_{A-} - \Phi_{B+})/\sqrt{2}$. It is a combination of sp^1 hybrids on A and B sites that point opposite to the other atom. These hybrid orbitals are ready to overlap with an H atom each, such as in the acetylene C₂H₂ molecule, or with other C atoms such as in carbyne, which is a 1D carbon chain. The last four electrons of the C₂ molecule occupy the doubly degenerate π_u bonding state (see Fig. 1b) obtained by combining the 2p_x orbitals and the 2p_y orbitals. These electrons form two π bonds.

Other hybridizations of the 2s and 2p valence orbitals may be formed. The most symmetric combinations correspond to the sp^2 and sp^3 hybrids illustrated in Fig. 2. In the first case, each carbon atom forms three sp^2 hybrids, by mixing the 2s orbital with 2p_x and 2p_y orbitals. In graphene and graphite, the sp^2 hybrid orbitals have maxima of probability density along three directions at 120° in the xy plane. They form σ bonds with neighboring atoms. sp^3 hybrids are combinations of all valence orbitals. In diamond, each atom forms four such hybrids along four directions at 109.5° in space with tetrahedral symmetry.

Dimensionality and system symmetry critically determine electronic behavior, and carbon in this respect shows more versatility than any other chemical element. This is seen in the electronic density of states around the Fermi level (E_F) for different carbon species. C₆₀ is molecular and has localized electronic states giving sharp delta functions in the DoS (Fig. 11a), although these broaden somewhat in fullerite crystals due to inter-molecular coupling. Nanotubes have 1D-dispersed states along their lengths giving rise to characteristic spiked van Hove singularities (Fig. 8). The conjugated hexagonal 2D-lattice of graphene gives symmetric parabolic DOS around the Fermi level due to graphene's conical bands (Fig. 5e), while the DOS plots of graphite and diamond reflect their more complex 3D symmetry. These different electronic behaviors are now discussed in more detail.

Fig. 1 (a) Variation of the 2s (dot-dashed line) and 2p_z (dashed line) atomic orbitals on site A along the axis z of the C₂ molecule. The solid line curves represent the Φ_{A+} (thick line) and Φ_{B-} (thin line) sp¹ hybrid orbitals, (b) Formation of the electronic levels of C₂ from the 2s and 2p levels of the atoms. The highest σ_g and the π_g levels are unoccupied.

Diamond

When carbon atoms are brought together to form a solid, their 2s and 2p levels broaden and form energy bands. The formation of these bands is illustrated in Fig. 3 for the case of diamond. At large interatomic distance, the bands are narrow and conserve most of the 2s and 2p characters of the individual atoms. When the distance decreases, the width of the bands increases and their s and p characters start to mix. At some distance, there is a crossing between the bottom of the band that originates from the 2p level, and the top of the band that originates from the 2s level. From now on, one may consider that the electronic states result from the σ overlapping of sp³ hybrid orbitals. By reducing the interatomic distance further, a gap opens between σ bands that have acquired bonding and antibonding characters, respectively. There are four hybrid orbitals per atom, giving rise to two states in each of the bonding and antibonding bands. Each band may therefore accommodate four electrons, due to spin degeneracy. Since there are four electrons per atom, the bonding band is full, the antibonding band is empty, and the system is a semiconductor. The so-called hybridization gap that separates the bonding and antibonding σ bands increases with decreasing distance. Interestingly enough, this picture remains qualitatively correct for the tetrahedral sp semiconductors that adopt the same diamond structure. From the decreasing interatomic distance in going from Ge to Si to C, one may understand the increase of their band gap. The picture also remains qualitatively correct for tetrahedral amorphous carbon.

For a crystalline material, the most complete description of the electronic states is provided by its band structure. A theoretical band structure of diamond is shown in Fig. 4b for Bloch vectors parallel to a principal diagonal of the cubic cell (ΓL line) and parallel to an edge of the cubic cell (ΓX line). The valence band extends from -22.6 to 0 eV. The width of the hybridization gap at the Γ point is 7.4 eV. There are four branches in the valence band, the two atoms per unit cell of diamond (Fig. 4a) bringing two bonding σ states each. The symmetry of the wave function along the ΓL and ΓX lines is high enough to allow for a twofold degeneracy of the top valence branch and the bottom conduction branch. The computed minimum band gap is 5.6 eV. It is an indirect gap, corresponding to a transition between the Γ point and the minimum of the bottom conduction branch along ΓX. The gap is so large that diamond does not absorb any visible radiation. Pure diamond is transparent, as a consequence.

(c) Energy band diagram of a hydrogen-terminated diamond surface showing Negative Electron Affinity (NEA) of the surface and, upon exposure to ambient air, formation of a two-dimensional hole gas through Charge Transfer Doping. μ_{Atmos} is the electrochemical potential of adsorbed molecules that trap valence electrons from the diamond, causing upward band bending and creation of a two-dimensional hole gas (2DHG) just below the surface. Image (c) adapted from Crawford KG, Maini I, Macdonald DA, Moran DAJ (2021). Surface transfer doping of diamond: A review. *Progress in Surface Science* 96: 100613. doi:10.1016/j.progsurf.2021.100613.

The σ bonds in diamond are very strong. As a result, its Young modulus for uniaxial strain applied along a fourfold symmetry axis is 1.05 GPa, one of the hardest materials measured (see ultrahard fullerites below). Switching from AB-layer stacking in cubic diamond to ABC- lowers the symmetry and results in the rare hexagonal carbon phase, Lonsdaleite (De and Pryor, 2014; Kraus et al., 2016; Turneure et al., 2017).

Diamond can be doped with other elements beside carbon to create donor and acceptor states, but this is difficult to achieve due to diamond's high density and strong σ bonds. Boron is the standard dopant for p -type conductivity, its optical activity giving a distinct blue color. While phosphorus and other elements such as arsenic show n -type character it remains difficult to n -dope diamond, which has limited diamond's development for devices. This is despite its high carrier mobilities ($1945 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ for electrons and $2285 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ for holes (Gabrysch et al., 2011)) and breakdown field (13 MV/cm), rendering it interesting for high power devices (Umezawa, 2018). The most common natural dopant in diamond is nitrogen, and of particular note is the negative nitrogen-vacancy defect (NV^- center) in diamond, which has optically detectable spin transitions and allows highly sensitive local field measurements (Dolde et al., 2011).

Hydrogen terminated diamond surfaces show negative electron affinity (NEA), meaning the vacuum level lies below the conduction band minimum (Himpsel et al., 1979; van der Weide et al., 1994). As such, excited electrons spontaneously emit from the surface, of interest in applications such as cold cathodes for electron microscopy (Kleshch et al., 2016). Introducing cationic species to hydrogen-terminated diamond surfaces (such as CO_2 dissolved in surface water, NO_2 , or molecules such as fullerenes or F4-TCNQ) results in shallow p -type conductive states in the diamond subsurface (surface transfer doping (Crawford et al., 2021), see Fig. 4c).

For further reading on diamond see the entry elsewhere in this encyclopedia on "CVD diamonds and superdiamonds".

Graphene and graphite

Graphite is the most common 3D allotrope of pure carbon. It is constructed from a stacking of atomically thin layers with a honeycomb structure named graphene (Fig. 5a). Graphene has another entry of the encyclopedia dedicated to it. The high cohesive energy of graphite (Table 1) comes almost exclusively from the strong σ interactions between the sp^2 hybrids and the less strong π interactions between the $2p_z$ orbitals (interatomic distance is 0.142 nm). The atomic layers are bound together by weak van der Waals forces (interlayer separation is in the range $0.33\text{--}0.36 \text{ nm}$). Consequently the electronic interactions between layers are weak and the electronic structure of the whole 3D crystal is mostly driven by that of the individual planes.

Graphene consists of a hexagonal array of carbon atoms in a plane. The repeat unit cell (Fig. 5a) is a rhombus containing two equivalent carbon atoms (same chemical environment). The electronic properties of isolated single graphene sheets are described in detail in other entries in the encyclopedia. A short summary of the very particular electronic properties of this atomically thin bi-dimensional crystal is made in Fig. 5. The planar geometry of the graphene layer implies that the symmetry group contains the $+z/-z$ mirror plane operation. The electronic band structure of a single graphene layer can then be sorted: σ states are symmetric under the mirror plane operation, and π bands are anti-symmetric.

Fig. 5c shows the calculated electronic band structure of graphene. Both σ and σ^* bands are plotted in black. The bonding σ states are formed by overlapping sp^2 hybrid orbitals oriented along the C–C bonds, with energy approximately in the range -21 to -5 eV . The anti-bonding σ^* states lie above $+1 \text{ eV}$, i.e., $\sim 6 \text{ eV}$ above the bonding states. This is close to the band gap observed in diamond, which only has σ and no π -bonding. Unlike the case of diamond, in graphene this gap is bridged by the π and π^* states that originate from the $2p_z$ orbitals, perpendicular to the atomic layer. The dispersion of the bonding π states (from the bottom of the band to the Fermi level, in red in Fig. 5c and d) is quite large ($\sim 8 \text{ eV}$), symptomatic of a high degree of delocalization of the electrons. These delocalized electrons are associated with the electrical conductivity of graphene and graphite. The anti-bonding π^* band (in blue) has an energy above the Fermi level (close to -2 eV).

The π band and one π^* band cross at the corner K of the Brillouin zone (Fig. 5c and d). The Fermi level coincides with this crossing point, and since there are no electronic states exactly at the Fermi level, graphene is therefore technically a zero-gap semiconductor rather than a semi-metal. The low energy electronic properties are then totally controlled by these two π and π^* bands, and it is reasonable to describe the electronic properties of graphene with such a "two band model" (Fig. 5d). The states close to E_F have momentum located in the vicinity of the K point, at the boundary of the Brillouin zone. The bands in this area are linear, a behavior very peculiar to graphene which is responsible for much of its surprising electronic properties. The electronic density of states (Fig. 5e) shows van Hove singularities located around $\sim 2.5 \text{ eV}$ above and below E_F (corresponding to the shoulders at point M of the Brillouin zone) and a typical V-shaped density close to E_F (corresponding to regions close to K).

Different allotropes of graphite exist according to the stacking arrangement of the graphene planes. The most common crystalline form of graphite, discovered by J. D. Bernal in 1924 (Bernal and Bragg, 1924), has the stacking illustrated in Fig. 6a: alternate graphene layers are offset, with one of the two carbon atoms in the graphene unit cell lying above an atom in the sheet below, the other lying above a hexagon. These alternating layers are often labeled "A" and "B" and the Bernal geometry is often also called AB-stacked graphite for that reason. In Bernal graphite, there are four atoms per unit cell (two per layer), each of them forms three σ states and two π states, of which half have a bonding character. The major difference with graphene is that the four atoms are now in different chemical environments: two of them have atoms located directly above and below them, whereas the other two have the center of hexagons. The corresponding hexagonal Brillouin zone is sketched in Fig. 6b. Since the Bernal crystal is genuinely three-dimensional, the former K point of the reciprocal plane of graphene is now replaced with the axis along k_z in the corner of the zone: the H–K line.

As for graphene, the σ states of graphite are combinations of sp^2 hybrid orbitals and the π states are combinations of $2p_z$ orbitals. Since the interactions between planes are weak, the bonding σ and anti-bonding σ^* electronic bands of the two layers in the unit cell are quasi-degenerate and remain located far from the Fermi level (Fig. 6c). This means they participate only marginally to the

Fig. 5 (a) Graphene 2D hexagonal structure. The primitive cell, that contains two carbon atoms, is highlighted. The two atoms are equivalent (same chemical environment) (b) Brillouin zone of graphene in the reciprocal plane. The high-symmetry points K and M are specified. (c) The band structure of graphene calculated with the local-density approximation and plotted along the high-symmetry directions. The Fermi level is exactly at the crossing of the two bands π and π^* that are plotted in red and blue. The σ bands are in black. (d) 3D view of the pure p_z bands. They cross at the corner K of the Brillouin zone. The Fermi level coincides with the crossing energy. (e) Typical electronic density of states of graphene. The density is exactly zero at the Fermi level (set to 0 eV), which is why graphene is a zero-gap semiconductor.

electronic response of graphite. Electronic interaction between the graphene sheets is much more efficient with the out-of-plane $2p_z$ orbitals contained in the π -bonds, and these orbitals form two bonding bands and two antibonding bands. Consequently, they appear as two pairs of bands split around the Fermi level, by the interlayer coupling.

Fig. 6d shows this in more detail. Along the H–K line, there is a series of pockets of electronic (bands below E_F) and hole states (bands above E_F). The overlap is small (around ~ 30 meV) between the π and π^* bands. The consequence is that graphite is a semi-metal. It is a poor electrical conductor (room temperature resistivity of crystalline samples $\rho_l \approx 10 - 6 \Omega\text{m}$) because the number of charge carriers (electrons and holes) is small, contributing to its use in resistance heaters (Okada et al., 2017).

Graphite intercalation compounds (GIC) are composed of planes of intercalant atoms or small molecules separated by a few graphitic sheets, in a sequence that repeats periodically along the c -axis as in a superlattice. The number of graphitic layers stacked between two successive intercalant planes is called the stage of the GIC. The intercalants can be electron donors (such as alkali

Fig. 6 (a) Graphite unit cell with Bernal AB-stacking. (b) First Brillouin zone of graphite with its high-symmetry points. (c) The band structure of Bernal graphite calculated with the local-density approximation and plotted along the high-symmetry directions. Four electronic π bands are in the vicinity of the Fermi level (set to zero). The σ bands (nearly doubly degenerate) lie below. metals) or electron acceptors (such as bromine), shifting the graphite Fermi level up and down respectively. Depending on the intercalants used and their concentration, a huge class of GICs can be realized with tailored electronic properties, ranging from metals $\rho \approx 10 - 8 \Omega\text{m}$ to insulators (Ebert, 1976; Li et al., 2019).

Carbon nanotubes

Carbon nanotubes are cylindrical forms of graphene or graphite. A single-wall nanotube (SWNT) is composed of one graphene sheet rolled up into a cylinder. SWNTs preferentially pack together in the form of bundles of 10–200 tubes. The van der Waals attraction between the tubes has very little effect on the electronic density of states of the individual components. Multi-wall carbon nanotubes (MWNTs) are composed of several single-wall tubes arranged coaxially, with interlayer distance ~ 0.34 nm. The electronic structure of large multi-wall nanotubes is similar to that of graphite; roughly speaking, they behave like a semimetal. In principle, about one third of the coaxial layers are supposed to be metallic (see below), the remaining being semiconducting. Under high potential bias, each tubular layer of a multi-wall nanotube can transport a current $\sim 20 \mu\text{A}$ before breaking (Collins et al., 2001), consistent with the capability of MWNTs to withstand high current densities of over 10^9 A/cm^2 .

To understand the electronic properties of a single-wall nanotube, the zone folding model is very practical, based on a joint analysis of nanotube geometry and graphene electronic structure. The circumference of the nanotube is a direct lattice vector of graphene, wrapped around in such a way that its two ends coincide. This vector is commonly called the chiral vector. It is developed as $\mathbf{C}_h = n\mathbf{a}_1 + m\mathbf{a}_2$, where n and m are two integer numbers (the wrapping indices of the nanotube), and $\mathbf{a}_1$ and $\mathbf{a}_2$ are the two Bravais vectors of the graphene layer (Mintmire and White, 1995). This construction is illustrated in Fig. 7a and b. The diameter of the nanotube d is given by $d = \frac{\sqrt{3}a_c}{\pi} \sqrt{n^2 + m^2 + n \cdot m}$, and the chiral angle θ given by $\tan(\theta) = \frac{\sqrt{3}}{2m + n}$.

As in graphene, the electronic structure of a nanotube close to the Fermi energy is dominated by π and π^* states. A SWNT can be “metallic” or semiconducting, depending on its wrapping indices. When the radius is not too small, the rule is that the (n, m)

Fig. 7 (a) Schematic representation of a single-wall nanotube. The example is the (7,4) nanotube. (b) The unfolded canvas of the tube is a rectangular region, showing the construction of its chiral vector $\mathbf{C}_h = 7\mathbf{a}_1 + 4\mathbf{a}_2$. The translation symmetry vector $\mathbf{T}$ is perpendicular. The helical angle θ of the tube is indicated. (c) When $n-m$ is a multiple of three the point K of the Brillouin zone of graphene is included in the selection of k-points of the zone folding model. (d) Consequently two bands with a nearly linear dispersion are crossing at E_F . The tube is “metallic.” (e) When $n-m$ is not a multiple of three the point K is not included in the selection. Bands are no longer crossing at E_F . (f) The nanotube is semiconducting.

Table 2 Electronic properties of single-wall (n, m) nanotubes.

“Zig-zag” if $m = 0$, otherwise “Chiral”		“Armchair”
$n - m \neq \mathcal{M}(3)$	$n - m = \mathcal{M}(3) \neq 0$	$n - m = 0$
Semiconductor	Tiny gap ($E_g \sim \cos(3\theta)/d^2$)	Truly metallic
$E_g = S_{11} = \frac{2\gamma_0 a_{cc}}{d}$	$M_{11} = 3S_{11}$	$\rho = \frac{2\sqrt{3}a_{cc}}{\pi^2\gamma_0 d}$
$S_{22} = 2S_{11}$		

d is the diameter, θ is the chiral angle, $a_{cc} = 0.142$ nm, E_g is the bandgap of the semiconducting tubes, $\gamma_0 = 2.9$ eV is the π -electron interaction., and ρ is the density of states per atom at the Fermi level for the truly metallic tubes (or in the pseudogap plateau for the tubes exhibiting the tiny gap).

nanotube is metallic if $n-m$ is a multiple of three, otherwise it is semiconducting (Table 2). The rolling of 2D graphene into a 1D tube results in the collapse of the 2D graphene band structure onto a series of 1D lines (Fig. 7c) whose spacing and orientation depends on the nanotube chirality. For metallic tubes, the Bloch vector at the point K (see Fig. 7c and d), where the π and π^* bands of graphene meet, satisfies cyclic boundary conditions around the circumference: $C_h \cdot \mathbf{K} = q \cdot 2\pi$, with q an integer. Similarly to graphene, the electron bands close to E_F in a “metallic” nanotube are linear. They give rise to a plateau of density of states around the Fermi level (Fig. 8 left). At either sides of this plateau are spikes in the density of states, called van Hove singularities (vHs). These correspond to the top of the band located below the two linear bands, and the bottom of the next band above them. The energy separation of these two vHs is inversely proportional to the nanotube diameter, and is very useful for spectroscopic analysis (see below). Each band crossing the Fermi level contributes one quantum $2e^2/h$ to the conductance of the nanotube when it is connected to two macroscopic electrodes. This means that the minimum resistance of a metallic SWNT is $h/4e^2 = 6.45$ k Ω (two bands are crossing E_F). Below room temperature, the intrinsic resistance of an isolated nanotube increases upon cooling.

In the situation when $n-m$ is a not multiple of three, the point K does not satisfy the cyclic conditions of the wrapping: the electronic bands of the nanotube never meet and a gap is opened (see Fig. 7e and f). Similarly to “metallic” nanotubes, the gap is flanked by two vHs (S_{11} in Fig. 8 right), and the value of this gap is inversely proportional to the tube diameter. In addition, a second pair of vHs is present in the density of states, separated by the energy S_{22} .

More reliable calculations of the electronic properties of nanotubes validate the predictions given by the zone folding model, as shown in Fig. 9. Only a small correction must be noted: in reality only the armchair (n,n) nanotubes are truly metallic, the “metallic” nanotubes with $n-m$ a non-zero multiple of three exhibit a tiny gap that scales as $1/d^2$. The evolution of this secondary gap has been observed by scanning tunneling spectroscopy (Ouyang et al., 2001).

The most remarkable characteristic of the SWNTs, directly linked to their 1D periodicity, is the presence of the van Hove singularities (vHs) in the density of states. These spikes are fingerprints of the nanotube structure and can be probed by optical absorption, resonant Raman spectroscopy, electron-energy-loss spectroscopy (EELS), and scanning tunneling spectroscopy. An example of optical absorption spectrum of bundles of SWNTs with 1.3 nm average diameter is shown in Fig. 10a. The peaks ~ 0.7 and 1.3 eV are due to transitions between the first pair $E_{11}S$ and the second pair $E_{22}S$ of van Hove singularities that border the gap of the semiconducting nanotubes. The absorption peak ~ 1.9 eV is due to interband transitions $E_{11}M$ across the plateau of

Fig. 8 (a) Typical shape of the electronic density of states of a "metallic" nanotube (the 7,4 nanotube in Fig. 7). It is constant over a wide energy range around E_F separated by two van Hove singularities (vHs). (b) Shape of the electronic density of states of a semiconductor nanotube. The gap (value S_{11}) is separated by a first couple of vHs. There is a second pair of vHs further from E_F with energy separation S_{22} .

Fig. 9 Complete tight-binding ($\sigma + \pi$ electron) density of states of the semiconducting (13,6) chiral nanotube and the metallic armchair (10,10) nanotube. The atomic structures of these two nanotubes are illustrated on the top. The band structure of (10,10) is shown in the right-hand side panel. The Fermi level is set at zero energy.

density of states of the metallic nanotubes (see Fig. 7). In general, the spacing of the van Hove singularities is inversely related to the nanotube diameter, and plots of this are commonly referred to as Kataura plots (Kataura et al., 1999) (see Fig. 10b).

When performing resonant Raman spectroscopy, nanotubes with van Hove spacings corresponding closely to the energy of the exciting laser will have their signal enhanced by many orders of magnitude over non-resonant tubes. In practice this means that Raman spectroscopy of SWNTs only shows vibrational peaks for tubes which are in resonance. SWNTs have a low frequency vibrational mode detectable in Raman spectroscopy corresponding to a periodic change in the nanotube radius, called its radial

Fig. 10 (a) Optical absorption spectrum of bundles of SWNTs, with interband transition peaks superimposed on the wing of the broad π -plasmon absorption band. The same spectrum after removal of the plasmon background is shown in the inset. (b) Kataura plot showing spacing between van Hove singularities in the nanotube density of states for different tube diameters and chiralities as a function of their diameter. Image from [Wikipedia.org](https://www.wikipedia.org).

breathing mode. The frequency of this mode is inversely proportional to the tube radius. It is therefore possible to modify the x-axis of the Kataura plot to show instead the radial breathing mode frequency. In this way, knowing the excitation laser energy used for the resonance Raman measurement and the frequency of detected radial breathing modes allows precise identification of the nanotubes present and in resonance in the sample.

Similar to graphite, bundles of single-wall carbon nanotubes can be doped by intercalation between and/or inside the tubes, using either electron acceptors (*p*-type doping (Grigorian et al., 1998)) or donors (*n*-type doping). In all cases, there is a charge transfer, a noticeable modification of the optical response of the nanotubes, and a strong reduction of the electrical resistance of the bundles. The Fermi level of the nanotube can be shifted by more than 1 eV by electron or hole doping. In the case of alkali intercalation, for instance, the Fermi level moves up across the conduction bands of the nanotubes. As a consequence, the lowest optical transitions S_{11} , S_{22} , and M_{11} , are progressively suppressed as their final states become occupied. The corresponding resonant behavior of the Raman cross section disappears at the same occasion. Other mechanisms to shift the Fermi level in nanotubes include molecular surface absorption, electrochemical gating, substitutional doping and defect formation (Monthieux, 2011).

For further reading see entries elsewhere in the encyclopedia covering “Electronic Properties of Rolled-up Nanoarchitectures” and “Optical Properties of Rolled-up Nanoarchitectures”.

Fullerenes and fullerites

Fullerenes are hollow carbon cage molecules, the cages constructed from carbon atoms connected to three neighbors forming a closed or partially closed surface made up of polygons with carbon atoms at their vertices. Following Euler’s formula, for a closed cage structure the number of pentagons minus number of heptagons must equal 12 (Anderson, 2023). C_{60} (Buckminsterfullerene) is the most abundant fullerene (Kroto et al., 1991). Its atoms are located on the surface of a sphere of ~ 0.7 nm diameter forming a truncated icosahedron. They sit at the vertices of 12 pentagons, the edges of which have a length of 0.145 nm, slightly longer than the 30 bonds (0.140 nm) shared by the hexagons that connect the pentagons. $2p$ orbitals locally normal to the molecular surface form π states, and $sp^{2+\epsilon}$ hybrids, which point along the C–C bonds form σ states, with some mixing of both characters due to the strong curvature of the molecule. The electronic levels of C_{60} are shown in Fig. 11a. In total there are 60 π states, of which 30 are occupied. Similarly, there are 90 σ occupied states. Due to the icosahedral symmetry of C_{60} , most of the electronic levels are degenerate. The highest occupied molecular orbital (HOMO) of C_{60} has h_u symmetry (fivefold degeneracy), and the lowest unoccupied molecular orbital (LUMO) has t_{1u} symmetry (threefold degeneracy). The HOMO–LUMO separation is 2 eV. The states near the HOMO–LUMO gap have a dominant π character. Because both the HOMO and LUMO wave functions are antisymmetric with respect to the inversion center of the molecule, the HOMO–LUMO transition is dipole forbidden. The lowest measured optical transition of the C_{60} molecule is ~ 3 eV. Due to its lower symmetry, the C_{70} molecule has eight different bonds, whose lengths vary between 0.137 and 0.147 nm. The one-electron states of C_{70} are singly or doubly degenerate, the HOMO–LUMO separation is 1.8 eV. The smallest fullerene, C_{20} consists of 12 pentagons and no hexagons, is almost entirely sp^3 -bonding character due to the high local curvature, and as a result is extremely reactive and unstable (Prinzbach et al., 2000).

Fullerites are solids realized by close packing of fullerene molecules. The cohesion of these crystals is assured by van de Waals interactions between the fullerenes. In the solid, the electronic levels of the individual fullerene molecules are only weakly broadened by intermolecular coupling; they form bands with little dispersion, typically 0.5 eV. The C_{60} crystal (Fig. 11b) is a semiconductor with a 2.2 eV band gap, fcc at low temperatures but increasing in symmetry to simple cubic above 260 K when

Fig. 11 (a) Electronic energy levels for isolated C₆₀ (b) Conventional face-center cubic cell of the C₆₀ fullerite, (c) Room temperature photoemission spectrum, and (d) C1s excitation EELS spectrum of C₆₀ thin film, revealing the distribution of occupied and unoccupied electronic states, respectively.

individual C₆₀ molecules freely rotate about their center of mass (Lubenets et al., 1997). The distribution of the occupied states in C₆₀ fullerite is clearly revealed by photoemission spectroscopy (Fig. 11c), whereas the unoccupied states can be probed by inverse photoemission and also by EELS (Fig. 11d). High pressure compression of fullerites can result in polymerization and cross-linking between fullerene neighbors forming sp³-bonds (Serebryanaya et al., 2001). The resultant ultra-hard fullerites are able to plastically deform diamond (Popov et al., 2014).

Like all molecules, the fullerenes are highly-correlated electronic systems. An effective Coulomb energy U can be estimated by $U = I - A - \Delta$, where I is the ionization energy (7.5 eV), A is the electron affinity (2.7 eV), and Δ is the HOMO–LUMO separation (2 eV). This gives $U \approx 2.8$ eV as the bare value for an isolated fullerene, although this can be reduced by 1 eV in the solid state due to screening effects.

Fullerenes can be doped, by incorporation of atoms endohedrally in the cage centers (Popov et al., 2013), e.g., Gd@C₈₂ (Zhang et al., 2020), and by atomic substitution (heterofullerenes), such as C₅₉N (Andreoni et al., 1996). X-ray photoemission provides valuable information on the electronic structure of these compounds (Erbahar et al., 2016). Inversely, various fullerenes and endohedral metallo-fullerenes can be encapsulated inside single-walled carbon nanotubes. In these remarkable structures, called carbon peapods, the encapsulated molecules form 1D chains (Smith et al., 1998). The fullerenes in a peapod can be more densely packed than in bulk fullerite. Their electronic levels form bands, which hybridize partly with the electronic states of the host nanotube.

Fullerites can be doped by intercalation of atoms and small molecules in the octahedral and tetragonal cavities of their crystal lattice. Since the electron affinity of the fullerene molecules is high, they easily accept electrons from the intercalants. In the case of C₆₀, the phase diagram of the A_xC₆₀ compounds, with A an alkali metal, is remarkably rich. The x electrons given by the ionized alkali atoms fill in the t_{1u} LUMO-derived band, which may accommodate six electrons. This simple rigid band-structure picture predicts that all the A_xC₆₀ compounds should be metallic except for $x = 0$ and 6. In fact, there are strong electron correlation effects

in fullerites, as mentioned above, which invalidate this model, and only A_3C_{60} is metallic. Remarkably enough, most of the compounds having that composition are superconductors. The critical temperature T_c increases with increasing the ionic radius of the intercalant: 18 K in K_3C_{60} (Hebard et al., 1991), 30 K in Rb_3C_{60} , and 33 K in $RbCs_2C_{60}$ (Tanigaki et al., 1991). The raising of T_c is due to the narrowing of the LUMO-derived band with fullerene lattice spacing, and the resulting increase of density of states at the Fermi energy.

Miscellaneous synthetic carbons

Although many metastable pure carbon structures have been theoretically predicted, very few have been experimentally synthesized or isolated. Fully sp -hybridized carbon structures are notoriously unstable, but individual sp -bound C_{18} carbyne rings have been produced on surfaces and show alternating single-triple bond character (Kaiser et al., 2019; Scriven et al., 2020) (see Fig. 12a), while extended linear carbon chains have been successfully encapsulated inside carbon nanotubes (Shi et al., 2016). Localized triple carbon bonds (two carbons sharing one σ - and two orthogonal π -bonds) are short with a characteristically high vibrational frequency in the range 1800–2200 cm^{-1} .

Mixed sp/sp^2 layered structures, graphdiyne and graphynes, have been produced through organic synthesis routes (Hu et al., 2022; Leytham-Powell and University of Colorado Boulder, 2022; Li et al., 2010; Liu et al., 2022). Graphdiyne consists of a layered lattice of benzene rings, connected via triple-bonded C_2 pairs (see Fig. 12b). Since the back bonds on the benzene rings are single σ -bonds, there is no extended conjugation between the rings and the material behaves as a semiconductor.

Disordered carbons

Carbon may form different partially disordered solids depending on the preparation technique used and experimental conditions, all of which have considerable technological interest. Amorphous carbons form a wide range of structures intermediate between the two extreme allotropic forms, diamond and graphite. Each can be characterized by the sp^3/sp^2 ratio (there may be a small proportion of sp^1 states as well), and different degrees of local order and hydrogenation. The density of a carbon sample can be determined from the frequency of its $\sigma + \pi$ plasmon measured in EELS (Ferrari et al., 2000), by the formula $\omega_p = ne^2/\epsilon_0 m^*$, where n is the valence-electron density, directly related to the atomic density, ϵ_0 is the dielectric permittivity, and m^* is the electron effective mass ($\approx 0.87 m_e$) (LiBassi et al., 2000). EELS and C1s photoelectron spectroscopy give access to the sp^3/sp^2 fraction (Fallon et al., 1993; Grossman et al., 1996). Experiments indicate that the sp^3/sp^2 ratio increases linearly with the atomic density of the sample.

Fig. 12 (a) C_{18} sp -bound carbyne rings produced on substrates through debromination of $C_{18}Br_6$, and (b) γ -graphyne or graphdiyne structure consisting of sp -bonded C_2 units interconnecting hexagonal sp^2 -rings. From Panel (a) Scriven LM, Kaiser K, Schulz F, Sterling AJ, Woltering SL, Gawel P, Christensen KE, Anderson HL, Gross L (2020). Synthesis of cyclo[18]carbon via debromination of $C_{18}Br_6$. *Journal of the American Chemical Society*. 142: 12921–12924. doi:10.1021/jacs.0c05033.

When the sp^2 and sp^3 sites are intermixed at the atomic scale, the electronic structure of amorphous carbon near the Fermi level is dominated by π and π^* states, arising from the sp^2 sites, and to a much lesser extent, by disorder-induced σ -band tails due to both sp^2 and sp^3 sites. When the sp^3/sp^2 ratio is large, as in most diamond-like carbons, one speaks of tetrahedral amorphous carbon. This material is hard, electrically insulating, and transparent. The minority sp^2 sites tend to form small clusters; they control the band gap, which can be reduced by a factor of 2 or more with respect to crystalline diamond. In sp^2 -rich systems, the sp^3 sites can be randomly and uniformly distributed among the atoms, leading to a non-graphitic disordered structure. The electrical conductivity of such a sample is small and exhibits a semiconducting behavior. By heat treatment, and concomitant migration of the sp^3 defects, graphite-like amorphous carbon is obtained. It can be viewed as a random assembly of nanometer-sized turbostratic entities, partly embedded in a matrix of fourfold atoms. The electronic structure and the conductivity, then, depend critically on the size distribution of the turbostratic entities and on their degree of disorder.

Conclusion

In his 1975 short story collection “The Periodic Table,” Primo Levi wrote that “Every element says something to someone (something different to each) like the mountain valleys or beaches visited in youth. One must perhaps make an exception for carbon, because it says everything to everyone” (Levi, 2000). Carbon is the earliest recorded non-metal chemical element in human history (approaching 4000BC charcoal was used for metal ore reduction by the Egyptians and Sumerians (CAER, 2012)), and yet continues to reveal new surprises, resulting in two Nobel prizes in the last 30 years. In this chapter we have shown that from only a few simple tools that carbon provides—the possibility of π -bonding, the capability to hybridize into sp , sp^2 , and sp^3 configurations—a vast wealth of structures and electronic behaviors emerge, spanning the full range of condensed matter physics.

A key driver for the electronic behavior of carbon materials is local symmetry. In C_{60} the molecular icosahedral symmetry results in highly degenerate molecular states, the origin of superconductivity observed in doped fullerite crystals. The hexagonal 2D-lattice of conjugated p_z -orbitals in graphene results in conical electronic bands that touch at the Fermi level and give rise to the amazing Dirac fermionic behavior of electrons in graphene. The 1D-nature of nanotubes creates sharp van Hove singularities in their electronic density of states that dominates their optical response, with the tube symmetry determining whether it behaves as a metal, semi-metal or semiconductor.

The electronic behavior of carbons links directly to other material properties, such as the high thermal conductivity, optical transparency and toughness of diamond. As such the flexibility in geometry and electronic structure gives rise to carbon materials that span the range of materials parameters, representing some of the mechanically strongest and weakest materials known, the best insulators and conductors, and the most optically transparent to the blackest of blacks (Wikipedia, 2022b). Carbon continues to surprise (witness the discovery of superconductivity in twisted graphene bilayers (Cao et al., 2018)), and with continued advances in synthetic carbon chemistry and doping promising more to come, Primo Levi’s words hold as true today as when they were first written.

Abstract

As a chemical vapor deposition technique that can achieve outstanding coating conformality on complex structures, atomic layer deposition (ALD) has received great attention in both academic research and industrial applications since its invention in the 1960s and 1970s. Herein, the basic principle of ALD—based on a sequence of self-limiting gas-solid-surface reactions—and different ALD approaches are summarized, namely temporal vs. spatial and thermal vs. plasma-enhanced. Subsequently, the variety of materials deposited by ALD is highlighted, and some ALD-coated nanostructures are presented. Finally, a short but comprehensive introduction is given to the most recent developments and achievements in ALD or closely related methods.

Introduction to and general principle of ALD

Atomic layer deposition (ALD) is a coating technique to deposit thin films and is closely related to the chemical vapor deposition (CVD) method. In contrast to normal CVD, where one or more precursors are decomposed or reacted in the gas phase, ALD bases on sequential, separated self-limiting gas-solid surface reactions of two or more gaseous precursor species. A binary ALD cycle consisting of two half-reactions is sketched in Fig. 1A.

Four steps can be identified:

1. *Pulse 1*: The substrate's surface is occupied by certain surface groups. Vapor of precursor α is brought to the substrate's surface.
2. *Purge 1*: After the completed, self-terminating surface reaction, the non-used precursor α molecules as well as the reaction by-products are pumped away, and the reaction chamber is purged.
3. *Pulse 2*: At this point, the substrate remains in an intermediate surface state. The second precursor β is pulsed into the ALD chamber and reacts in a self-limiting manner with the exposed parts of precursor α chemisorbed to the substrate.
4. *Purge 2*: After the completed gas-solid surface reaction, the reaction chamber is purged from the by-products and the non-used precursor β molecules.

If the two precursors α and β are well-chosen, the surface groups after one ALD cycle allow for repeating the cycle. In every ideal ALD cycle, the same amount of material—a fraction of the material's monolayer—is deposited depending on the accessible surface sites, the precursor size, and the precursor and substrate chemistry. Typical growth rates, usually defined as *growth per cycle* (GPC), observed for ALD processes range from 0.1 to 1.5 Angstrom per ALD cycle. Thus, the total deposited film thickness can be defined by the number of cycles during an ALD process (Fig. 1B). Note, the thin film growth via ideal ALD is not limited by the absolute mass transport of precursor molecules as long as self-termination of the surface reactions is reached. In general, ALD is diffusion-limited, which means, on the one hand, no line-of-sight from the precursor source to the substrate is required (Fig. 1C). On the other hand, the molecules need sufficient time for diffusion and surface site reaction. Consequently, homogeneous and conformal coatings with controlled sub-nm thickness can be achieved even on three-dimensional (3D) features at the expense of extended process times. Depending on the precursors chosen, a plethora of materials can be deposited by ALD, ranging from oxides, nitrides, fluorides, sulfides, and phosphides as well as selenides, tellurides to pure elements or mixtures of the aforementioned materials. In the "[...] case study for the trimethylaluminum/water process," Puurunen describes the most important features and main characteristics of ALD in detail in her review article in 2005 (Puurunen, 2005). An updated version of the review, including more than 2300

Fig. 1 (A) Schematic of an ALD cycle with two different precursor species. One ALD cycle consists of a pulse of precursor α which reacts in a self-limiting manner with surface groups. After purging the reaction chamber, the precursor β is brought to the substrate presenting an intermediated surface. Precursor β reacts there again in self-terminating behavior, and deposits the desired material. Subsequently, the reaction chamber is purged again. Since the (resulting) surface groups after one ALD cycle can react with precursor α again, a sequential deposition routine allows for exact thickness control by adjusting the number of cycles. (B) Due to the self-limiting nature of the ALD reactions, a constant GPC and thus a linear growth as the function of cycle number is achieved. (C) Schematic comparison of a conformal surface reaction-limited ALD process and a deposition process which is mass flux limited by a line-of-sight coating, e.g., sputtering.

references and focusing on the crystallinity of ALD deposited film was published in 2013 (Miikkulainen et al., 2013). In general, ALD has the capability to provide continuous, pinhole-free films with a low content of residual impurities. However, by employing the different surface chemistry of precursors on various materials, ALD can be tailored in such a way that the deposition of nanoparticles and clusters or in an area-selective fashion is feasible (Grillo et al., 2017; Mackus et al., 2014). Note, Steve George's review (George, 2010) summarizes in a short and comprehensive manner the major trends and developments in ALD in the last two decades. Specifically, the review addresses new ALD process technologies, such as plasma-enhanced ALD (PEALD), atmospheric-pressure ALD, spatial ALD, area-selective ALD (AS-ALD), and (polymer) molecular layer deposition (MLD), to name a few of them.

The origin of ALD dates back to the 1960s and 1970s when the principle of ALD was developed and investigated in parallel in the former Soviet Union and Finland under the name "Molecular layering" and "Atomic Layer Epitaxy," respectively. However, the initial ALD research activities in the Soviet Union went unnoticed for a long time and are still poorly cited compared to the fundamental studies in Finland (Puurunen, 2014). An ALD community-driven virtual project on the history of ALD (VPHA) (Ahvenniemi et al., 2017) summarizes 22 publications—voted by the community as significant early achievements in the field of ALD—in chronological order. Note, "early" is defined therein as before 1986 when a review article about ALD or atomic layer epitaxy was published by authors not treated as the pioneers of ALD. In detail, Shevjakov, Aleskovskii, and Kol'tsov reported on metal chloride reactions with water for the deposition of TiO_2 , GeO_2 , and later SiO_2 and PO_x from 1965 to 1975. At that time, Suntola and Antson (Suntola and Antson, 1977) patented the principle of atomic layer epitaxy for depositing compound films from elemental precursors, e.g., ZnS from Zn and S. However, other materials such as SnO_2 and GaP are listed, as well, and H_2S as a potential hydrogen source is suggested. In the follow-up patents and applications, molecular inorganic precursors were introduced, e.g., TaCl_5 and AlCl_3 with H_2O for depositing Ta_2O_5 and Al_2O_3 , respectively, as well as ZnS from ZnCl_2 and H_2S . Note, the first industrial application of ALD or atomic layer epitaxy was in fact ZnS, which was used for the fabrication of thin film electroluminescence displays employed at Helsinki airport from 1982 until 1998. In the mid of the 80s, metal-organic precursors were introduced in ALD for the first time to deposit III-V semiconducting GaAs and AlAs by utilizing AsH_3 with $\text{Ga}(\text{CH}_3)_3$ and $\text{Al}(\text{CH}_3)_3$, respectively. In the early 1990s, the more general term ALD gained acceptance over atomic layer epitaxy because many ALD reactions did not result in epitaxial or even crystalline growth. Due to the high purity of the deposited materials, the ability to coat even complex structures without shadowing effect, and the precise control of the film thickness, ALD came into the focus of the semiconductor industry in the 1990s for the deposition of high- κ dielectrics. Using materials with higher dielectric constant than the classical silicon dioxide allowed for further miniaturization of metal-oxide-semiconductor field-effect transistors (MOSFET) structures. Together with the industrial interest in ALD, the research landscape also revived, and great progress was made in the last 20 years in precursor and reaction chemistry. As of 2022, a community-driven process database hosted and maintained by Kessel's group at Eindhoven University of Technology gives a tabular literature overview of the published processes.¹ Moreover, a regularly updated list of review articles related to ALD can also be found there. ALD is outstandingly suited for the coating of (nano) structures with high aspect ratios—the ratio of geometrical characteristic length and diameter—because of its self-limiting nature.

¹<https://www.atomiclimits.com> [accessed 02.04.2022]

In such substrates, e.g., opals, nanoporous membranes, bio-materials, and nanoparticles, ALD is often the only suitable technique to reach a conformal coating without shadowing effects (Knez et al., 2007; Bae et al., 2011; Detavernier et al., 2011). Besides basic research in physics, chemistry, and material science, ALD is also a state-of-the-art technique in different industry fields, such as semiconductor and solar cell energy.

Overview

In order to offer a more comprehensive understanding of ALD, this section firstly presents several basic forms of ALD, namely thermal and plasma-enhanced ALD as well as temporal and spatial ALD in Sections “Thermal vs. plasma-enhanced ALD” and “Temporal vs. spatial ALD”, respectively. Since ALD has received attention from basic research to industry in recent years, a variety of ALD processes utilizing various precursor types have been explored to deposit materials comprising the majority of elements in the periodic table as summarized in Fig. 2. However, one of the most important points for a successful ALD is the metal precursors used. A typical metal precursor contains one type of metal atom per precursor, and several characteristics, namely high reactivity, volatility, and good thermal stability over a wide temperature range, have to be fulfilled. State of aggregation, costs, ease of handling, and toxicity are side aspects but not to be neglected. Note, the ligands’ properties determine the properties of the metal precursor and thus can be used to tailor the precursor chemistry. Although the potential advantages of organometallic precursors are their high volatility and low growth temperature, one of the disadvantages is that their thermal decomposition often takes place already at low temperatures, which may induce non-self-limiting CVD components besides the ALD growth and high impurity contents. Main material classes deposited by ALD are presented in Sections “ALD of oxides,” “ALD of nitrides,” “ALD of metals and elements,” “ALD of sulfides, phosphides, fluorides.” Subsequently, approaches synthesizing multi-component films (Section “ALD of ternary and quaternary components”) and, following, in situ characterization methods in ALD processes (Section “In situ characterization of ALD processes”) are discussed. Finally, a selection of applications profiting from the unrivaled ability of ALD to deposit conformal coatings on nanostructures will be presented.

Thermal vs. plasma-enhanced ALD

ALD bases on (at least) two binary reactions of a precursor α with a precursor β , often denoted as reactants, to prepare the desired material. A common example is the deposition of aluminum oxide by the reaction of trimethylaluminum (TMA, $\text{Al}(\text{CH}_3)_3$) with water. The two half-reactions can be written as:

The driving force of this exothermic reaction is the formation of a strong Al-O chemical bond. Similarly, other thermal oxide processes, such as those for TiO_2 and ZnO , are also driven by a conducive change in the Gibbs free energy. However, other ALD reactions might require additional energy, such as heat, to overcome the energy barrier for the chemical reaction of the precursor with the surface. In the ideal ALD, a temperature range, the so-called *ALD window*, can be defined in which the growth per cycle is constant (Fig. 3). Below the ALD temperature window, either CVD caused by precursor condensation or a suppressed growth can be

Fig. 3 Sketch of the ALD window including the processes when the ALD window is left to lower and higher temperatures.

identified; whereas, above the ALD window, precursor decomposition and desorption or loss of functional groups can lead to CVD and reduced growth, respectively. Note, the applicable reaction temperatures are generally limited by constraints in precursor vapor pressure and stability, reaction chamber design, and substrate. To overcome this thermodynamic obstacle without excessive heating, additional external energy is needed which can be provided, e.g., by a highly reactive species delivered from plasma or radical source in at least one half-cycle of the ALD reaction. In addition to the inherent higher reactivity of the plasma radical, the ions' kinetic energy, surface recombination rates and energies, and the total energy flux of the plasma radiation contribute to the additional energy term in a PEALD process.

Already in the first ALD review by Suntola and Hyvärinen in 1985 (Suntola and Hyvärinen, 1985), the authors predicted the occurrence of plasma-supported ALD to render new reaction pathways. Six years later, a first plasma-enhanced, also called plasma-activated, ALD process of GaAs employing hydrogen radicals prepared in a plasma source was reported. However, it lasted almost one decade until the ALD community took up the topic when PEALD was used for the deposition of Ti and Ta. From there, novel processes and precursors as well as plasma sources and reactor types have been developed, enabling ALD scientists to deposit materials hardly achievable by thermal ALD, e.g., elemental metals and semiconductors, or to improve the deposition quality and to reduce the impurity content of the deposited films. The reviews of Profijt in 2011 (Profijt et al., 2011) and Knoops in 2019 (Knoops et al., 2019) present a comprehensive summary of the development of PEALD in the past 20 years.

On the one hand, PEALD reveals several advantages compared to thermal ALD: First, as aforementioned, the plasma, with its highly reactive species, provides an additional energy contribution. Consequently, the thermal energy, i.e., temperature, needed to deposit an ALD thin film with the same properties as in a thermal ALD process can be lowered. Such a reduction in temperature is of particular interest if temperature-sensitive substrates, e.g., polymeric ones, need to be coated. Second, several publications report on improved material properties deposited by PEALD compared to thermal ALD, such as impurity content, density, and optical or electronic characteristics, to name a few. Third, some metal-organic precursors are not usable in thermal ALD; thus, novel ALD reaction pathways are conceivable. For instance, some metal-organic compounds with sufficient vapor pressure and thermal stability reveal a vanishing or negligible reactivity to water, rendering them unsuitable for thermal ALD. However, by utilizing a highly reactive oxygen plasma, these compounds can be employed as ALD precursors, opening new reaction schemes. Additionally, hydrogen plasma can provide highly reducing species to allow for depositing metals not feasible by thermal ALD reductants. Fourth, due to the highly reactive plasma species, more reactive surface sites can be prepared during the ALD plasma half-cycle leading to an overall increased growth rate for some processes.

On the other hand, PEALD also has some drawbacks compared to thermal ALD. The major disadvantage is the non-usability of PEALD to coat high aspect ratio nanostructures or highly porous substrates conformally. Recombination of radicals at the surface with other species or radicals is accompanied by losing their high reactivity. Since the probability of surface collision and, consequently, recombination is significantly increased for these kinds of high surface area substrates, the local flux of radicals inside the porous structure or at 3D structures is reduced as a function of the diffusion depth and geometry, respectively; thus, the deposition becomes non-conformal. By varying the plasma parameters, such as power, duration, and pressure, to name a few of them, the conformality of the PEALD process can be controlled and improved for aspect ratios up to ~ 30 . However, PEALD cannot compete with thermal ALD where aspect ratios of 1000 and more or even branched porous substrates with non-ballistic transport paths can be coated conformally at sufficiently long diffusion and purge times. Another impediment of PEALD is the possibility of damage or surface alteration upon the plasma half-reaction. The highly reactive species of the reactant can alter the chemical properties of the substrate surface via oxidation and nitridation, leading to an unwanted interface. Energetic ions impinging on the surface during the plasma may lead to bond-breaking and defects in the deposited materials or on the substrate, as well as to charge accumulation in the thin film. Another source of plasma-induced damage is the highly energetic ultraviolet (UV) radiation occurring during the plasma. This radiation can alter the properties of polymeric substrates but also potentially introduce defects and degrade surface passivation. Lastly, the plasma source and the control of which render the ALD system much more complex, prone to error, and expensive. Furthermore, the parameter space for process optimization, e.g., temperature, (partial) pressure, and precursor dose, is expanded by the plasma parameters, e.g., power and duration.

Temporal vs. spatial ALD

The invention and development of ALD sparked several concepts of ALD reactor designs. The scientists in the former Soviet Union started their research on ALD in a reactor chamber with a stationary substrate exposed to a sequence of different precursors. In contrast, Suntola drafted in his initial patent (Suntola and Antson, 1977) a concept of a rotating disk holding the substrate which crosses areas of stationary precursor vapors during spinning. Thus, two different major operation modes can be defined, namely temporal and spatial ALD (Fig. 4).

In temporal ALD, a heated reactor is loaded with a stationary substrate, and stationary valves control the precursors flow by opening and closing one after the other, separated by a purge/pump time. Adjusting the duration of the individual steps in the ALD cycle is needed to achieve sufficient precursor doses to saturate all surface groups but also to remove all non-used precursors and reaction by-products to avoid reduced growth and CVD, respectively. Scale-up of thermal temporal ALD processes is achieved in so-called batch reactors in which several substrates are stacked over each other and coated simultaneously. Of course, precursor doses and purge times have to be increased according to the increased surface area of the reactor and substrate. Note, PEALD in batch reactors is hampered because of the stacked arrangements of the substrates (see Fig. 4). Specifically, the long diffusion paths without line-of-sight between substrate and plasma source increase the probability of surface collision and recombination; thus, reducing the number of reactive species deep inside the batch.

In spatial ALD, the substrate moves through different fixed and stationary precursor zones separated by a zone where the purging occurs. For instance, this could be a rotating substrate, as in the Suntola patent (Suntola and Antson, 1977). Still, it could also be a substrate transported (back and forth) through a line of different precursor zones separated by an inert gas zone (see Fig. 4). A fixed substrate with a movable precursor injection head is another concept of spatial ALD. Note, in all cases, not only thermal ALD but also PEALD operation is feasible. The main advantage of spatial ALD compared to temporal ALD is the absence of purge time needed to empty the reaction chamber. Since the chemical surface reaction typically occurs in the millisecond time range, only the mechanical transfer time between two separated precursor zones limits the total cycle time of ALD. Of course, at more complex structures, the exposure time—which is the time the substrate has to remain in one precursor zone—has to be extended to fulfill the ALD criterion of self-limitation at all available and accessible surface groups. A good overview of different concepts of spatial ALD, such as roll-to-roll reactors where a flexible substrate is moved from one roll to another roll by guide rollers running several times through two different precursor zones chamber, rotating disks reactors, and drum reactors, to name a few of them, is given by Poedt

Fig. 4 Schematic overview for different reactor types. Upper box: Types of ALD reactors operating in a temporal fashion, e.g., thermal and thermal batch ALD, PEALD, but also ALD systems for particles coatings. Lower box: ALD reactor types working in the spatial regime, such as floating substrate or rotating disk reactors.

et al. (Poodt et al., 2011). In terms of economic aspects, spatial ALD comes with a more complex reactor design with mechanical parts compared to temporal ALD. On the other hand, the reactor wall is coated in temporal ALD, and usually, much more precursor than needed for the self-limiting surface reaction is provided. However, the precursor excess, which is not reacted, is then purged and thus wasted. In other words, the efficiency of precursor utilization is increased for spatial ALD concepts compared to temporal ones. Consequently, the running costs of the spatial ALD coating, namely the expenses for precursors, could be significantly reduced compared to temporal ALD. Moreover, complex gas abatement systems for cleaning the exhaust gas of non-used (and potentially explosive or toxic) precursor are superfluous.

ALD of oxides

Metal oxides have been deposited from a huge variety of inorganic and organic molecular precursors, such as halides, alkoxides, alkyls, amides, and beta-diketonates, just to name a few. As reactants, water, ozone, and oxygen plasma have been mainly used (Miikkulainen et al., 2013). Note, processes with water often bases on a protonation reaction of the precursor ligands, whereas reactions with ozone and oxygen plasma are often combustion-like. Alternative oxidant precursors, such as hydrogen peroxide, alcohols, and N_2O , have been reported in literature as well. Furthermore, special ALD processes have been explored which do not contain a separate dedicated oxygen reactant but use another metal precursor as oxygen source. Specifically, metal alkoxides or carboxylates have been employed for such processes that are treated as more gentle to the underlying substrate since a highly oxidizing reactant is waived.

Historically, the major driving force for ALD of oxides was the need for advanced high- κ dielectrics as gate oxides in MOSFET and as capacitor dielectrics in dynamic random-access memories (DRAM). Nowadays, ALD is recognized as a state-of-the-art deposition technique in the industrial fabrication of these complex logic and memory devices due to its inherent conformality and film thickness control, often outperforming other deposition techniques, such as CVD and sputter coat (Hwang, 2014). Within the last decades, the device structures changed from 2D to nanostructured 3D, rendering ALD the method of choice. The majority of the deposited dielectrics by ALD are binary oxides, e.g., HfO_2 , Al_2O_3 , ZrO_2 , to name a few of them. Also, doped oxides, e.g., Sr- or Ba-doped TiO_2 ($SrTiO_3$, STO; $BaTiO_3$, BTO) or nanolaminates consisting of zirconia and alumina are of particular interest for DRAM applications (Coll and Napari, 2019).

Recently, ALD in general has aroused interest in more fields and applications: Special attention has been paid to moisture diffusion barrier layers, e.g., Al_2O_3 , ZrO_2 , and SiO_2 , to encapsulate and to protect organic-light emitting diodes (OLED). Other transition-metal oxides, namely MO_3 , WO_3 , and V_2O_5 have been employed as hole contact in OLEDs. Further, lithium oxide compounds have already been deposited for battery applications. Besides, in organic and flexible electronics and displays, ALD of transparent conducting oxides, for instance, Sn-doped In_2O_3 (ITO) and Al-doped ZnO (AZO), has taken hold in industry.

Other properties of oxide thin films, e.g., magnetism, ferroelectricity, or multiferroics, deposited by ALD have been investigated in detail in basic research but also for applications. For example, multiferroic (doped) hafnia layers have been studied as potential resistive RAM (ReRAM).

Apart from binary oxides, plenty of doped oxides, e.g., $In_2O_3:Zr$, $SnO_2:Sb$, $ZnO:Ga$, and other ternary or quaternary oxides (for further information see Section "ALD of ternary and quaternary components"), such as $PbTiO_3$, $SrTa_2O_6$, $SrBi_2Ta_2O_9$, $La_{1-x}Ca_xMnO_3$, to name a few of them, have also been produced via ALD.

ALD of nitrides

Typically, metal nitrides are hard, chemically resistant, sometimes catalytically active, and often electrically conductive materials. Since the pioneering work of ALD-deposited metal nitride published in 1988 (Hiltunen et al., 1988), they have become the material class with the 2nd most number of ALD publications after ALD oxides. Metal nitrides, such as Si_3N_4 , TaN, TiN, and WN_x , are often used as diffusion barriers for water as well as oxygen and metal diffusion, respectively, in the microelectronics industry. Another increasing interest in ALD of nitrides exists in research on superconductivity, e.g., TiN, NbN, or mixtures of them. The reported nitrides deposited by ALD can be generally divided into two categories according to their electrical properties: (1) nitride dielectrics or semiconductors such as BN, AlN, GaN, Si_3N_4 , Ta_3N_5 , Cu_3N , InN, Zr_3N_4 , Hf_3N_4 , LaN, LuN; (2) metallic nitrides such as TiN, Ti-Si-N, TaN, NbN, MoN, Ti-Al-N, WN_x , WN_xC_y , Co_xN , Sn_xN .

The most typical ALD nitride processes are based on the reaction of metal chloride (or other halide) precursors with NH_3 as a reactant. A prime example is the reaction of $TiCl_4$ with NH_3 to deposit TiN. However, these processes need relatively high temperatures (typically in the range of 350–500 °C) and suffer from residual impurities of the respective halogens. Both issues can be addressed simultaneously by replacing the halide precursor with a metal-organic precursor. Specifically, metal-organic alkyl amide-based compounds can be used for metal nitride deposition, e.g., TiN, ZrN_x , MoN_x , HfN_x , TaN_x , and WN, at lower temperatures (150–250 °C) compared to the halide-based processes and avoiding halogen residues at the same time but at the cost of additional carbon impurities (Miikkulainen et al., 2013). To grow nitrides containing main Group III elements, namely Al, Ga, and In, by ALD, alkyls which contain a direct metal-carbon bond have been used.

NH_3 serves as a reductant of the metal center in the precursor during the ALD reaction. Generally, NH_3 leads to the stable nitride with the highest metal oxidation state. For instance, to achieve the conductive TaN over the dielectric Ta_3N_5 an additional reducing agent to NH_3 , such as elemental Zn or Me_3Al needs to be implemented during the ALD process (Miikkulainen et al., 2013). Different reducing agents, such as hydrazine (Me_2NNH_2) and tert-butylamine, have been employed for the deposition of TaN and TiN as well.

PEALD can ease the deposition of metal nitrides with a lower oxidation state and often reduced amount of impurities compared to thermal ALD. The deposition temperature can be lowered, novel precursor chemistries could be used, e.g., $\text{Nb}(\text{N}^t\text{Bu})(\text{NETMe})_3$ instead NbCl_5 for depositing NbN , and the number of tunable process parameters, e.g., plasma power, pressure, and gases, can be increased to improve and tune the thin film properties. Instead of using gaseous NH_3 , nitrogen-hydrogen mixtures with adjustable ratio have been exploited in PEALD. The hydrogen-plasma serves as reductant during the ALD process whereas the nitrogen-plasma resembles the nitrogen source. Note, amide compounds, i.e., $\text{Ti}[\text{NMe}_2]_4$, in combination with reducing hydrogen (plasma) have been studied to deposit the corresponding nitride, i.e., TiN , without the need of an additional nitrogen source.

ALD of metals and elements

Metals deposited by ALD are often more challenging to achieve in high quality compared to oxides and nitrides. Consequently, relatively less research—and even fewer industrial applications—utilizing metal ALD has been carried out compared to ALD of metal oxides in the past. However, in order to fulfill Moore's law, CMOS devices need to be further down-scaled, and the architecture becomes more complex. Hence, increased demands for the precision and conformality of the deposition process are set. These requirements can be easily met by ALD leading to a number of potential applications in the device fabrication, not only for oxides and nitrides as aforementioned, but also for metal deposition. Tungsten and copper are essential metals for plugs and interconnects, respectively, in CMOS technology and have been in focus for ALD for a while. Whereas, tungsten layers can be deposited by the reducing WF_6 with diborane, silanes, or hydrogen (plasma) for years. The reliable deposition of metallic copper remained challenging until novel reaction pathways have been developed, e.g., $\text{Cu}(\text{dmap})_2$ or $\text{Cu}(\text{hfac})_2$, in combination with a plethora of reductants including H_2 , H_2 plasma, diethyl zinc, formic acid, formaldehyde, etc. Other applications of metals (Ru, Co, Ta, Ni, and Ti) deposited by ALD in barriers and liners for interconnects or electrical contacts and gate electrodes are conceivable nowadays. Note, the introduction of 3D gate structures, such as fin- or nanowire-based gate-all-around FETs makes the use of ALD processes inevitable for reliable device fabrication (Hagen et al., 2019; Hwang, 2014).

Noble metals, especially in the form of (nano)particles, are of interest for catalysis applications. In contrast to electronic device preparation in which continuous—ideally pinhole-free—thin films are aimed for, isolated particles and islands are often preferred for maximum catalytic performance. By employing the difference in surface energy of the metal to be deposited and the substrate, the ALD process parameters can be tuned to adjust particle-size distribution. Especially, platinum-group metals, e.g., Pt, Ru, Pd, Ir, are comparably easy to reduce in their oxidation state—after precursor adsorption of the metal precursor at the substrate's surface—and thus can be deposited in their metallic state without the need of high temperatures or strong reducing agents.

Three different types of reaction schemes for the reduction step have been mainly explored: First, “normal” reducing agents, e.g., H_2 , NH_3 , and N_2/H_2 as well as plasma of which, have been applied not only on platinum group metals but also on some more reactive metals. Molecular H_2 has been widely used for the ALD of some highly reactive metals, e.g., Cu, Ta, Ti, and Sn, by reaction with their halides. NH_3 or nitrogen/hydrogen plasma was employed to deposit metallic films of cobalt and nickel. Second, metal deposition via an intermediated surface oxidation step by utilizing oxygen, ozone, water, or air as reactant for combustion of the adsorbed precursor. In other words, firstly, a metal oxide film is produced, followed by a subsequent reduction to metal by the next metal precursor pulse. This reaction is often supported by self-catalytic effects of the metallic thin films as well as a limited stability of the intermediated oxides. Third, other less common reducing agents have been investigated to deposit metals, such as zinc vapor, silanes, and boranes.

Note, further developing and optimizing processes for metals remain an important aspect of ALD. Specifically, metal-organic precursor development and the search for matching reductants are still ongoing for reliable metal deposition. Current materials of interest are the deposition of gold and silver. Moreover, understanding the interplay between substrate properties, e.g., surface energy, texture, and oxidation state, with the metal deposition process, specifically its initial nucleation, is essential to control and to tune the growth of metallic particles but also continuous thin films.

ALD of sulfides, phosphides, fluorides

Apart from the widely investigated oxides, nitrides, and metals discussed above, other binary compounds have also been explored and some of which have even been already put to applications.

As previously mentioned, the development of ALD was driven by the need for an optimized fabrication method for thin film electroluminescent displays containing ZnS. In detail, manganese- as well as rare and alkaline earth-doped ZnS films, have been used for monochromatic (yellow) and multi-color displays, respectively. Most recently, the development of advanced structures for “green” energy-related applications, such as photovoltaics or batteries, have been a driving force for ALD of sulfide materials. Especially the unique ability of ALD to conformally coat complex structures is advantageous to coat these (often porous) devices with a large surface area and to tailor the interfaces. For example, CdS and InS can be employed to deposit a buffer layer for energy band alignment in $\text{Cu}(\text{In,Ga})\text{Se}_2$ (CIGS) solar cells. The first deposition of ZnS based on elemental Zn and S. However, halides and, much more prominent, metal-organic precursors can easily react with hydrogen sulfide (H_2S) to form a metal sulfide at lower temperatures than needed for elemental precursors.

ALD of phosphides has been rarely reported: Only CoP has been developed as a catalyst to enable efficient water splitting, whereas AlP, GaP, and InP have gotten their position in semiconductor applications. Phosphorus is customarily delivered by its hydrides, e.g., PH_3 plasma. However, PH_3 decomposes seriously during plasma treatment so that excess P remains, which is hard to

eliminate in the following purge step and leads to an undesirable deposition. Therefore, the subsequent removal—for instance, by an additional H_2 plasma step—of the excess P would be the key to achieve ALD of phosphides (Zhang et al., 2020).

Metal fluorides, e.g., CaF_2 , SrF_2 , MgF_2 , LaF_3 , ZnF_2 , are important optical coating materials because they possess not only a low refractive index but also a high transmission at both UV and infrared (IR) wavelengths. The conformal characteristic of ALD coating renders it a perfect method to produce three-dimensionally shaped optical components. Furthermore, other metal fluorides, e.g., AlF_3 , have been employed as a protective coating on Li-ion battery electrodes. Similarly to phosphides, only a decent number of processes for ALD of fluorides has been reported because vaporous HF reacts with metal-organic precursors to form fluorides, e.g., AlF , MgF , NaF , ZrF_4 , etc., but it is highly toxic and corrosive, and thus needs dedicated ALD and laboratory equipment with high safety requirements. Nonetheless, alternatives have been explored: On the one hand, the in situ thermal decomposition of NH_4F to only locally create the HF and to avoid handling dangerous HF vapor has been suggested. On the other hand, vaporous TiF_4 and TaF_5 have been used as fluorine reactants in combination with a variety of metal-thd precursors. Unlike HF, these reactants are low vapor pressure solids and can thus be handled and stored more safely with fewer restrictions. Note, even the reactant carries another metal center, the impurity content of Ti and Ta is reported to be of minor nature.

ALD of ternary and quaternary components

The basic principle of ALD is based on two half-reactions forming a binary material. Hence, traditional applications of ALD rely on binary oxides. However, the binary process can be combined to form complex tailor-made materials containing three, four, and more elements, often referred to as ternary, quaternary, and quinary materials, respectively. Strategies to synthesize such complex materials by ALD include so-called supercycle schemes, co-dosing approaches, and multistep approaches (Vandalon, 2020; Mackus et al., 2019b), as illustrated in Fig. 5.

A regular binary ALD cycle (Fig. 5A) usually consists of sequential precursor pulses, exposure, or carrier gas purge for each half-reaction to form one ALD cycle. In a so-called supercycle deposition scheme, two or more binary ALD processes (running m - and n -times, etc.) are put together into a “larger” loop which itself is then repeated x -times (Fig. 5B). Depending on the number of m and n , the achieved compound can be tailored and divided as follows:

- (1) m and n are comparably small and equal (e.g., 1:1, 1:2, etc.): A ternary oxide, $\text{A}_x\text{B}_y\text{C}_z$, which is uniform and well-mixed in the deposited composition. The ratio between the different constituents can be slightly tailored.
- (2) $m \gg n$, or vice versa (e.g., 1:20, 1:50): A doped material can be achieved.
- (3) m and n are close but large (e.g., 20:20, 40:50, etc.): A so-called nanolaminate consisting of separated continuous thin layers is formed.

Accordingly, in the example of the reactions with diethylzinc (precursor β), trimethylaluminum (precursor γ), and water (precursor α) for depositing ZnO and Al_2O_3 , one can deposit by varying m and n : (1) a $\text{Zn}_x\text{Al}_y\text{O}_z$ ternary oxide thin film with tailor-made stoichiometry, (2) an Al-doped ZnO thin film which can be employed as transparent conductive oxide, and (3) a multilayer film of separated Al_2O_3 and ZnO layers. Also, the accordingly management of trimethylaluminum (precursor β) and O_3 (precursor α_1) plus titan(IV)isopropoxide (precursor γ) and water (precursor α_2) can respectively lead to $\text{Al}_x\text{Ti}_y\text{O}_z$, Al-doped TiO_2 , “ $\text{Al}_2\text{O}_3 + \text{TiO}_2$ ” nanolaminate too.

In the co-dosing approach, as shown in Fig. 5C, at least two precursors (e.g., β , γ) are injected simultaneously into the reaction chamber simultaneously. Alternatively, two precursors or reactants can be mixed in varying proportions in the precursor container or a dedicated volume and then injected together. A typical example of the co-dosing scheme is the ALD process for ZnO_xS_y . Both reactants, namely, H_2O and H_2S , are pulsed at the same time. By varying the concentration ratio of them, the resulting composition of the deposited materials can be tailored.

Fig. 5 Schematic overview of strategies leading to complex materials constituting more than two elements. Here, precursor α , β , γ are containing the target deposited elements A, B, C, respectively. Precursor α_1 and α_2 in the schematic diagram for supercycle can stand for the same precursor or two different precursors that contribute to the same deposited element A.

Supercycling and co-dosing can both be used for the deposition of multicomponent thin films. However, each of them has specific advantages and downsides. On the one hand, better mixing of the constituents in the sub-monolayer regime can be achieved by co-dosing compared to the supercycle approach. On the other hand, the simultaneous competing chemical reactions of the two precursors on the substrate—with different (and often not well-known) kinetics, reactivity, diffusivity, and adsorption behavior—complicate the prediction for process optimization and may vary in complex architectures like trenches. In contrast, such a potential drawback is avoided in the supercycle approach since the individual ALD reactions are separated. To which degree any of these effects play a role and to which extent they impact the properties of the prepared film varies from case to case.

The multistep approach (Fig. 5D) is also used to deposit multicomponent materials in ALD. Within this manner, a regular ALD process consisting of two half-cycle (AB-type) is extended by adding one or more steps (ABC-, ABCD-type, etc.). These additional steps can introduce an other constituent to the material, resulting in the deposition of a multicomponent material. Besides, the multistep scheme is often used to extend the operating window of ALD processes or modify the properties of a material. For example, in the low-temperature Pt ALD process using PtMe_3CpMe and O_2 plasma, the regular ALD process results in PtO_x at low temperatures. Low-temperature deposition of metallic platinum can be achieved by a multistep approach adding an H_2 plasma as a third step to reduce the PtO_x to metallic Pt.

Note, different process schemes can be combined with each other, e.g., the plasma-enhanced deposition of TiNbN uses the supercycle approach for varying the Nb/Ti ratio and the co-dosing approach during the plasma half-reaction of nitrogen and hydrogen to replace NH_3 .

In situ characterization of ALD processes

Optimization and characterization of ALD processes are typically performed as follows in daily lab routine: One of the ALD parameters, such as precursor or reactants, temperatures (chamber, precursor), characteristic times (pulse, exposure, purge), plasma parameters (power, duration), to name a few of them, is altered and a process of x -cycles is run. Subsequently, the properties of the deposited thin film, e.g., composition, morphology, thickness, and crystallinity, are ex situ characterized, and based on these results, the process is adapted. This procedure is repeated until the desired properties are achieved. However, such an approach could be rather time-consuming and the chemical reactions occurring at the surface during the process remain unknown.

Hence, in situ operation of characterization methods typically used afterward, but also other techniques not applied for thin film analysis can speed up the optimization process and may shed light onto the ALD reaction itself. Note, the self-limiting nature of the ALD half-reactions is beneficial for these kinds of studies since the surface remains for a long time in the same state allowing for long measuring/integration times without altering the surface. Most of the ex situ characterization methods used in the ALD community to characterize the deposited thin film or the process can also be employed in situ after modification of the ALD reaction chamber.

A summary of selected in situ methods and the targeted thin film and reaction analysis is given in Table 1 (Knapas and Ritala, 2013; Devloo-Casier et al., 2014; Dendooven and Detavernier, 2017).

Table 1 In situ methods and their targets.

Classification	Method	Target
Gravimetry/Mass	Quartz crystal microbalance to study the mass up-take/loss during half-reactions	• GPC • Conclusion to chemistry • Characteristic times (saturating and purging behavior) • Determination of precursor decomposition and surface etching reaction
Optical	Fourier-transform infrared spectroscopy (Surface-enhanced) Raman (Spectroscopic) Ellipsometry Optical emission spectroscopy	Molecular species during half-reactions in gas phase and on surface Molecular species on surface Film thickness evolution and refractive index Only for PEALD: species during plasma pulse
X-ray Analysis	Absorption spectroscopy Diffraction Fluorescence Grazing-incidence small-angle scattering Photoelectron spectroscopy Reflectivity	Probing the local atomic environment Crystallinity and grain size Film composition (and thickness) Surface morphology Surface composition and oxidation state
Charge/Mass	Quadrupole mass spectrometry	Thickness, roughness, density Gas phase molecules
Electron	Reflection high-energy electron diffraction	Growth mode and film thickness
Electrical/thermal	Resistance measurements Thermopile	Conductivity and growth mode Heat, reaction enthalpy

Nanostructures (high aspect ratio)

The separated self-limiting gas-solid chemical reactions of ALD feature two important aspects: (1) thickness control in the sub-nm regime and (2) conformal deposition in a non-line-of-sight fashion. Hence, ALD is ideally suited to overcoat complexly shaped nano- and microstructures since the gaseous precursor can easily penetrate into complex substrates, and the same film thickness at any position of the sample is deposited. ALD has proven its value in applications of conformal thin film deposition inside complicated geometries and 3D nanostructures, e.g., deep trenches, grooves, narrow pores, aerogels, etc. All of which are difficult to coat conformally by other deposition techniques such as sputter, pulsed laser deposition, and CVD.

Depending on the template structure, which needs to be coated, ALD can be used in exposure/stop mode operation. In detail, a valve between chamber and vacuum pump is closed immediately before the precursor is pulsed into the chamber. Then the reaction chamber rests in this state, and the precursor molecule can diffuse into the template structure. After a time t , the valve is opened again, and the chamber is purged. Note, determining the minimum duration of t —which can span even to a few minutes—is not trivial since several aspects such as sticking probability, temperatures, pressures, precursor doses, and aspect ratio, to name a few of them, influence the time needed to achieve full coverage of the surface (Cremers et al., 2019).

A plethora of nanostructured templates such as free-standing nanowires and -tubes, porous membranes, 3D printed scaffolds, assembled spheres/blocks, polymeric networks, CNT forests, and even biological substrates, e.g., viruses and butterfly wings, have been coated by ALD for various applications (Knez et al., 2007; Bae et al., 2011; Detavernier et al., 2011; Harberts et al., 2020). A selection of templates is highlighted in Fig. 6. Moreover, prominent applications of ALD and nanostructures used therein are summarized in Table 2.

In general, ALD on these nanostructured templates can fulfill several tasks:

- (i) Adding a “functional” layer to a non-active template that provides support, e.g., metal electrodes, photoactive layer, magnetic layers.
- (ii) Stabilization of underlying substrate, e.g., resistive coating against harsh environments, increasing mechanical stability, encapsulation.
- (iii) Changing the electrical nature of the surface, e.g., ionic conductivity, capacity enhancement, work function adaptation.
- (iv) Spacer layer or sacrificial layer between functional layers of interest.

A conformal coating of individual particles which are assembled on a substrate is hampered by the contact points between the particles but also between particle and substrate. (Miniaturized) Fluidized bed and rotary reactors agitate the particles in such a way that surface reactions all around the particles are achieved during the exposure to the precursor gases (Weimer, 2019). The coated particles can be later assembled into composite materials for application in similar fields as aforementioned, e.g., catalysis, electrode materials, and encapsulation, to name a few of them.

Fig. 6 Scanning electron microscopy (SEM) images of nanostructures that have been employed as templates for ALD. AAO facilitates the growth of nanotubes by ALD: The length, L , shown in the (A) cross-sectional image along the hole direction; the diameter and the interpore distance of the pore (B) can be controlled by the anodization process; the bright ring inside the pores in (C) are ZnO nanotubes embedded in the AAO membrane after ALD and Ar^+ sputtering removing the interconnecting layer on top. Pores appearing blocked are filled by redeposited material during the sputtering process. (D) Opal template from self-assembled polystyrene beads and (E) inverse opal achieved after ALD and calcination of the opal template. (F) CVD-grown CNTs and (G) nanorods prepared by a combination of lithography and reactive ion etching have been employed as templates for ALD. SEM images of (H) a 3D-printed scaffold structure utilized for cell culturing after ALD coating and (I) a cross-sectional image after focused ion beam cutting of the connecting tunnel.

Conclusion

As discussed and shown above, ALD is a versatile tool that allows for the deposition of thin films of a plethora of materials, e.g., metals, oxides, nitrides, ternary ones, etc., with sub-nm precision even on complex nanostructures.

The conformality is an ALD-inherent property which is usually treated as an advantage of ALD. However, in industrial applications, deposition on specified areas and no growth on others would ease the processing much because complex further lithography-(deposition-)etching steps can be saved. Since ALD bases on chemical (gas-solid surface) reactions, one could locally tailor or can employ the given surface chemistry in a sense to enable or to inhibit the growth (Mackus et al., 2019a). Such an AS-ALD could be achieved by either selective precursor/reactant adsorption on the growth area or surface deactivation to define the non-growth area. A prime example of selective precursor adsorption is the different chemical nature of -OH and -H terminated surfaces, i.e., oxides can be easily deposited at -OH groups but hardly at -H terminated surface sites. On the other hand, self-assembled monolayers or small inhibitor molecules, such as acetylacetone (Hacac), could be used to deactivate surface sites for reaction with the precursor. However, none of these processes could fully suppress the growth in the non-growth areas leading to a reduced selectivity. Hence, correction steps are introduced into the AS-ALD cycle, similar to the supercycle ALD approach mentioned before. For instance, repeated functionalization of the non-growth area or a (selective) etching step which removes deposited material in the non-growth area are experimental pathways to tackle the selectivity problem.

Especially the combination of AS-ALD with atomic layer etching—the counterpart of atomic layer deposition—is a promising approach. Similar to ALD, an atomic layer etching process (abbreviated in literature with ALE but not to be confused with atomic layer epitaxy) consists of (at least) two self-limiting steps. The first step modifies the top surface layer in a way that the surface

binding energy is weakened. In the 2nd half cycle—the etching step—the topmost layer is removed. Hence, a layer-by-layer etching is achieved. The etch rate per cycle is constant, and by setting the cycle number, the etched film thickness is defined. The lowered binding energy in the 1st step can be overcome by either using a plasma (ion bombardment) or a thermal chemical reaction in the 2nd step to remove the topmost layer. ALE was invented in the late 80s, but with further pushing Moore's law, an upswing has been taken in the last decade (Kanarik et al., 2015). A prime example of ALE is the etching of Si: Therein, the silicon surface is exposed to a chlorine species—either thermally or by plasma chlorination—forming Si-Cl bonds at the top. In the etching step, energy in the form of an Ar plasma is transferred to the substrate to form gaseous SiCl_2 with an evaporation energy of ~ 2.3 eV, which is significantly lower than the binding energy of 4.7 eV for pure Si. The plasma energy has to be chosen in such a way that the ion bombardment does not harm the bulk silicon but only the chlorinated surface. Hence, the etching stops once all chlorine species have been removed. Since a plasma etching step is used, the etching behavior is directionally similar to reactive ion etching. Most recently, significant progress in the development of thermal ALE processes has been achieved by introducing the isotropic, conformal behavior well-known from ALD by employing thermally driven chemical reactions in the 2nd step. Note, other energy sources to remove the modified surface layers are conceivable as well, such as photons and temperature or a combination of both as well as neutral beams of Ne (Kanarik et al., 2018; Fischer et al., 2021). Up to now, a variety of materials ranging from semiconductors, such as Si or GaAs, to metals, nitrides, and oxides can be etched by ALE. A database for ALE processes is available on the atomic limits blog, similar to the ALD database.²

All the processes mentioned above target the deposition (and etching) of inorganic materials. However, the general principle of ALD based on separated self-limiting reaction steps can also be used to deposit organic thin films or even hybrid organic/inorganic structures in combination with ALD. These processes are then called MLD (Sundberg and Karppinen, 2014; Meng, 2017). Compared to ALD, MLD is much younger and dates back to the early 1990s. In combination with ALD, in the 2000s organic/inorganic hybrid materials—metal centers covalently bonded to organic molecules—could be prepared for the first time with versatile and tunable material properties. MLD allows for the deposition of polymeric thin films, such as amides, imides, ureas, urethanes, esters, etc.

By its origin and definition, ALD utilizes gaseous precursor molecules to conduct the self-limiting reaction. However, it has been shown that ALD can also be conducted from liquid precursors in fluidic reactors, so-called liquid- or solvent-based ALD (IALD/sALD (Graniel et al., 2021)). Herein, the same prerequisites as for ALD from the gas phase have been defined, namely self-terminating, sequential surface reactions with a defined growth per cycle. On the one hand, IALD widens the field of applicable precursors and materials. Specifically, precursors which have no or only very few vapor pressures or are thermally not stable could be potentially employed to design IALD reactions. On the other hand, the setups as well as the purging step are more complex compared to the ALD based on gaseous precursors since the reaction chamber has to be rinsed with a solvent. As a consequence, the duration of the cycle times as well as consumptions costs for the purge medium, if not circulated, are higher than for conventional ALD but with the perspective of the utilization of cheaper precursors.

In summary, ALD and neighboring techniques, namely AS-ALD, MLD, ALE, and IALD, will be essential to push the limits in downscaling semiconductor devices further, to develop novel process schemes, to create and synthesize materials with tailor-made properties, and to open up new applications in various, such as 'green' energy, semiconductors, biology & medicine, optics, and sensors, to name a few of them.

Abstract

Substantial progress has been made in the field of combinatorial heterogeneous catalysis in the past decade. Combinatorial heterogeneous catalysis involves the computation-assisted design of diverse, high-density assemblies or arrays of potential heterogeneous catalytic materials, and high-throughput synthesis, characterization, and screening techniques. This chapter focuses on representative high-throughput preparation, characterization, and testing workflows that have recently been developed and employed in heterogeneous catalysis. It not only provides an introduction to combinatorial heterogeneous catalysis and the recent examples, but also highlights the areas in which advances are needed in the future.

Key points

- An introduction to combinatorial heterogeneous catalysis;
- Recent examples of high-throughput synthesis, characterization, and screening techniques for heterogeneous catalysis;
- A summary and outlook of the applications of combinatorial heterogeneous catalysis.

Introduction

The use of combinatorial methodologies to accelerate the research and development process in heterogeneous catalysis is increasing at a rapid pace in both industrial and academic laboratories (Xiang et al., 1995; Cawse, 2001; Hagemeyer et al., 2001; Seh et al., 2017). As shown in Fig. 1, combinatorial heterogeneous catalysis is a systematic screening of large heterogeneous catalytic materials libraries in a high-throughput fashion. It consists of three elements: large-scale event management, large library, and high-throughput screening. At the core of the term “combinatorial” is the “high-throughput” ability to prepare, characterize, and examine heterogeneous catalysts. For industry, the key drivers include the need to reduce the time-to-market for new and optimized catalysts and processes, increased probability of success due to the ability to perform far greater numbers of experiments than in the past, better intellectual property protection made possible by the thoroughness with which a given technical area can be explored, shorter more projects possible per unit time, the benefits of “early failure,” and the increased organizational efficiency resulting from improved data storage, access, analysis, and sharing. Similar advantages have already been addressed by the pharmaceutical industry, where long development times and high research costs have forced the development of high-throughput approaches to accelerate the drug discovery process.

Traditional methods for the discovery of new heterogeneous catalysts are not very efficient because discovery protocols are primarily trial-and-error processes. The ability to predict the required catalyst composition, structure, and formulation for a given chemical transformation is low and, for complex multi-component catalysts, almost nonexistent. In addition, there are many variables that affect a catalyst, including not only the elemental composition but also metal precursor types used, wet synthesis variables, method of post-treatment such as calcination conditions, presence and type/shape of catalyst support, and operating conditions such as temperature, pressure space velocity, and reactant gas composition. These variables are too numerous to adequately explore using conventional methods, especially in discovery programs, but also in catalyst optimization work where there may be fewer variables but where catalyst complexity (catalysts are often multi-component systems) is high.

Fig. 1 Combinatorial heterogeneous catalysis.

The high-throughput experimental process in combinatorial heterogeneous catalysis involves the computation-assisted design of diverse, high-density assemblies or arrays of potential catalytic materials (known as “libraries”), and high-throughput synthesis, characterization, and screening techniques that are characterized by using robotics and advanced computation (Senkan, 2001; Busch et al., 2002; Song et al., 2002; Sun et al., 2002). The integrated synthesis and screening of a plurality of catalysts in library format have been recognized as essential factors. Equipment miniaturization and integrated data management systems are also key aspects of successful workflows. The development and implementation of these methods require the involvement of unconventional engineering and computation resources not commonly available at chemical, refining, and petrochemical companies where heterogeneous catalysis is practiced. High-throughput research is optimally performed by interdisciplinary teams typically made up of chemists, engineers, and programmers (Bergh et al., 2003; Liu et al., 2003; Muller et al., 2003; Murphy et al., 2003; Jahnisch et al., 2004; Schunk et al., 2007; Ludwig, 2019).

The number of experiments that can now be performed using state-of-the-art high-throughput workflows can be an order of magnitude or higher than was possible only a few years ago using conventional research. For example, a high-throughput program can yield 50,000 experiments per year compared to 500–1000 experiments using traditional methods. This chapter is updated from its previous version published in 2005 (Hagemeyer and Volpe, 2005), and describes representative high-throughput preparation, characterization, and testing workflows developed and employed in heterogeneous catalysis over the last 5 years.

The hierarchical workflow in heterogeneous catalysis

The research and scale-up phases leading to the commercialization of heterogeneous catalysts are illustrated in Fig. 2 (Ortega et al., 2021). The high-throughput workflow can be divided into primary, secondary, and, in some cases, tertiary screening. Primary screening approaches are typically very high throughput qualitative or semi-quantitative screens performed on small samples often using unconventional reactor designs and are most often focused on discovery. The objective during this phase is to broadly screen a large and diverse set of material types that may perform the desired catalytic reaction. Discoveries termed “hits,” are then taken to the secondary screen, and, importantly, compositional space that is not useful is discarded. Although it is critical that primary screening results correlate with the real catalytic process, this can usually be accomplished by screening for qualitative trends and using relative performance rankings generated by using a simplified analog of the real process parameter. The primary screen must be designed to minimize both false positives and especially false negatives. Primary screening removes the key bottleneck in the R&D process.

Secondary screening is used for the confirmation and optimization of primary hits. In contrast to the primary screen, the catalyst form, reactor, and process analytics are designed to closely represent those of the real bench-scale material and reaction. The data quality and precision should be equivalent to that of a standard laboratory reactor since the goal is to observe small improvements in performance as a function of catalyst modification. Optimized hits, termed “leads,” are taken to the tertiary screening phase to generate commercial development candidates. If necessary, tertiary screening can be performed using conventional fixed-bed micro-reactors with full reactant and product detection and full mass balance, and in some cases is also parallelized. Secondary synthesis and screening technology have, in many cases, evolved to the point where the quality of the data obtained is equivalent to

Fig. 2 Schematic illustration of research and scale-up phases leading to commercialization in a heterogeneous catalyst development program (Ortega et al., 2021). From Ortega C, Otyuskaya D, Ras EJ, Virla LD, Patience GS, Dathe H (2021) Experimental methods in chemical engineering: High throughput catalyst testing - HTCT. *Canadian Journal of Chemical Engineering* 99: 1288–1306. Copyright 2021, John Wiley & Sons, Inc.

that obtained using conventional laboratory technologies. Accordingly, in some instances, pilot plant studies can proceed directly from secondary screening, without tertiary screening.

High-throughput synthesis technologies

The development of high-performance heterogeneous catalysts relies on the ability to control and optimize the catalyst's physical dimension and atomic structure, especially for nanocatalysts with large surface areas (Roy et al., 2021; Liu et al., 2021; Clayson et al., 2020). Synthetic advances to achieve high-quality nanomaterials with control over size, dispersity, phase, composition, and physical properties have driven progress toward heterogeneous catalysis. Multi-element nanomaterials hold great potential for various catalytic applications due to their widely tunable surface structures. However, conventional approaches are slow and rely on serendipity in search of optimized catalysts from complex multi-element nanomaterials. A general and robust synthetic strategy is highly desirable in investigating catalysts with increasingly complex compositions.

Recently, a high-throughput technique has been reported for combinatorial composition design and rapid synthesis of ultrafine multi-metallic nanoclusters (MMNCs) (Yao et al., 2020). They prepared and screened the PtPdRhRuIrFeCoNi compositional space using high-throughput rapid T shock synthesis coupled with scanning droplet cell electrochemistry (Fig. 3). The high-throughput synthesis includes two facile steps: (1) combinatorial composition design using metal precursors by formulation in solution phases; (2) uniform multimetallic nanoclusters synthesis by rapid thermal shock of the precursor-loaded carbon support. Then, the high-throughput electrochemistry was performed using a scanning droplet cell setup to rapidly screen for promising multimetallic nanocluster catalysts. This synthetic technique led to two promising catalysts, PtPdRhNi and PtPdFeCoNi, being quickly identified for the oxygen reduction reaction (ORR). The two nanoparticle catalysts were further carefully characterized using synchrotron X-ray diffraction (XRD) and transmission electron microscopy (TEM), and their catalytic properties were verified in a rotating disk setup (Fig. 3).

Due to its versatility and flexibility in energy saving, simplicity, and cost-effectiveness as well as the ability in controlling particle sizes, compositions, and structures, the wet-chemical technique has been well recognized to fulfill the mission of catalytic nanomaterial synthesis. However, conventional ways of high-throughput parallel synthesis require complex operation and costly equipment, which greatly restricts their further applications. In recent years, a microfluidic-based composition and temperature-controlling platform shows great promise in high-throughput wet-chemical synthesis. As shown in Fig. 4, a microfluidic-based composition and temperature-controlling platform was prepared to perform high-throughput wet-chemical synthesis (Hu et al., 2020). This platform employed 100-channel reactor arrays for wet-chemical synthesis with 5-level temperature gradients and utilized a microfluidic chip to prepare 20-level concentration gradients of the two reagents (50.85 mM of CoCl_2 water solution and 50.85 mM of NiCl_2 water solution) to generate CoNi bimetallic catalytic materials. They used X-ray photoelectron spectroscopy (XPS) to confirm the as-synthesized nanomaterials oxidation states. Scanning electron microscopy (SEM) and energy dispersive

X-ray spectroscopy (EDS) were further applied to characterize Co-Ni bimetallic solid materials synthesized under different reaction conditions. This work not only provides a dramatic increase in efficiency compared with the conventional approach but also enables a one-step investigation of the mild synthetic conditions required for a wet-chemical technique.

High-throughput characterization and screening techniques

The high-throughput characterization techniques are also essential in screening heterogeneous catalysts (Steinmann et al., 2022; Taylor et al., 2021; Pluchinsky et al., 2020). The physical and chemical properties of catalytic materials need to be systematically characterized to establish structure-property relationships for refining the catalyst optimization principle. The comprehensive characterization includes surface area and porous structure by Brunauer-Emmett-Teller (BET) analysis, particle size distribution via light and X-ray scattering, morphology via SEM or TEM, phase and structure by XRD and extended X-ray absorption fine-structure spectra (EXAFS), electronic structure by XPS and X-ray absorption near edge structure (XANES), and elemental

composition by inductively coupled plasma mass spectrometry (ICP-MS) and EDS, etc. Built on multichannel reactor design, sample automation, and large-scale data processing, high-throughput characterization by each of these techniques has become possible in recent years. More excitingly, some characterization techniques have been developed with *in-situ* or *operando* capability. For example, high-throughput *in-situ* EXAFS spectra was used to characterize a library of 91 catalyst precursors containing ternary combinations of Cu, Pt, and Au on γ -Al₂O₃ (Tsapatsaris et al., 2007). Valuable structure information was obtained by probing the local electronic structures, including coordination numbers, bond lengths, and static and thermal disorder. These results facilitated the understanding of CO oxidation rate over noble metal catalysts. 6 wt% Au on γ -Al₂O₃ displayed conversion rate oscillations related to reduction/oxidation cycles, indicating that its oxide or sub-surface layers deactivate the reactive surface.

One exciting advance in combinatorial heterogeneous catalysis over the past few years is high-throughput computational screening methods with high accuracy. In a typical example, Goddard et al. investigated the Haber-Bosch reaction mechanism ($\text{N}_2 + 3\text{H}_2 \rightarrow 2\text{NH}_3$) on two most active surfaces, Fe (111) and Fe (211) reconstructed surface. As shown in Fig. 5, they used density functional theory (DFT) to predict the free-energy barriers for the 34 most important 2×2 surface configurations and all 12 important reaction steps (Fuller et al., 2022). The predicted turnover frequencies were within experimental error. In order to make this strategy practical to screen more dopant candidates, they developed a hierarchical high-throughput catalysis screening (HHTCS) approach and then successfully identified the most important 4 reaction steps out of 12 for the two surfaces to examine

Fig. 5 Application of hierarchical high-throughput catalysis screening to Fe bcc (111) for Haber-Bosch NH_3 synthesis. (A) First layer (purple) and second layer (yellow) doping sites on the Fe-bcc (111) surface. (B) Free-energy landscape demonstrating the reaction barriers evaluated in HHTCS as colored lines. (C) Figure showing the results of the HHTCS screening sequence: candidates eliminated due to the vapor stability criterion are represented in purple, while those eliminated by the corresponding barriers shown in (B) are shaded in the same colors as in (B). Circles highlight the best dopant candidates (Fuller et al., 2022). From Fuller J, An Q, Fortunelli A, Goddard WA 3rd (2022) Reaction mechanisms, kinetics, and improved catalysts for ammonia synthesis from hierarchical high throughput catalyst design. *Accounts of Chemical Research* 55: 1124–1134. >50 dopant cases. Among the 34 transition-metal candidates and 17 non-transition metals (metalloids and main group metals), Co, Ni, and Si prefer subsurface sites. Ni doping was found to be the best, with a predicted 16-fold enhancement in the reaction rate. Finally, they proposed a new research direction to pursue increasing the accuracy via embedded correlated wave function techniques or *ad hoc* corrections.

The recent boom of machine-learning (ML) and deep-learning (DL) techniques has also advanced the high-throughput development of heterogeneous catalysts. As shown in Fig. 6, a Cu-Al catalyst has demonstrated for active and selective CO₂ electro-reduction to C₂H₄ with the aid of a ML-accelerated, high-throughput DFT framework (Zhong et al., 2020). The computational studies indicate that the Cu-Al catalyst provides multiple sites and surface orientations with near-optimal CO binding for both active and selective CO₂ electro-reduction. Guided by the computational prediction, Cu-Al electrocatalysts were synthesized and demonstrated efficient reduction of CO₂ to ethylene with the highest Faradaic efficiency in the reported literature. It clearly suggests the value of machine learning and computation in guiding the experimental design of complex multi-metallic heterogeneous catalysts.

Applications

Combinatorial heterogeneous catalysis is ideally suited for the discovery of novel noble metal and mixed metal oxide catalyst formulations for total combustion/volatile organic compound (VOC) removal, emissions control from stationary and mobile sources (NO_x abatement, CO oxidation, automotive three-way catalysis) due to the uncomplicated feeds and product mixes that often allows truly parallel detection and very high sample through-puts. Furthermore, combinatorial methods are advantageously applicable to multi-component catalysts (mixed metal oxides, alloys) for selective oxidation, hydrogenation, and dehydrogenation. The demand for higher sensitivities and efficiencies in refining has triggered the search for new zeolite structures by parallel hydrothermal synthesis. Additionally, improved fast analytical techniques are making it increasingly possible to perform high-throughput experimentation on complex real plant feeds. It is also promising for developing improved catalysts that are critical to clean energy-related

electrochemical conversion processes, including water splitting, fuel cells, and CO₂ capture and conversion. These electrocatalytic processes enable to transform of small molecules (e.g., CO₂, and water) and renewable feedstocks (e.g., biomass) into higher-value products (e.g., hydrocarbons, oxygenates, hydrogen, and ammonia) by coupling to renewable energy, and plays ever-increasing roles in addressing the environmental issues of modern society.

Published examples of extended and comprehensive combinatorial screening programs include ethane oxidative dehydrogenation leading to the discovery of Mo-V-Nb catalysts (Cong et al., 1999; Botella et al., 2003), combustion catalysis due to the demand for better low-temperature activity (Maier, 2003; Wang et al., 2021) in exhaust gas and air cleaning, automotive emission, stoves, and explosion prevention sensors, the water gas shift reaction aiming at high activity non-pyrophoric catalysts for fuel processors in future fuel cell-driven vehicles (Grubert et al., 2006), preferential CO oxidation in excess hydrogen (Laveille et al., 2013), propylene oxidation over supported metals (Kalyoncu et al., 2015), isobutane oxidation over mixed metal oxides (Paul, 2004; Otroshchenko et al., 2021), low-temperature light paraffin isomerization catalysts (Serra et al., 2003; Naqvi et al., 2018), methanol synthesis catalysts (Schüth et al., 2002), ethylbenzene oxidative dehydrogenation (Urschey, 2003), HCN synthesis over supported noble metals (Yamasaki et al., 2022), new anode and cathode formulations for polymer electrolyte membrane (PEM) fuel cells (Djilali, 2007) and CO₂ conversion (Zhong et al., 2020), and diesel tailpipe emissions control (Reşitoğlu et al., 2014; Sundermann and Gerlach, 2016).

Conclusion

Substantial progress has been made on combinatorial heterogeneous catalysis in recent years. Looking forward, it is clear that the field of combinatorial heterogeneous catalysis will continue to advance and be applied at an ever-increasing rate. Areas in which advances are needed and are being pursued include: creating high-throughput synthetic methods for precision synthesis of catalytic

materials with well-controlled atomic structures and nanoscale architectures, development of ML/DL-assisted computational methods with further improved accuracy and ability to predict catalysts in complex environments (especially for complicated liquid and electrochemical conditions), integration of multiple characterization tools with high-throughput *in-situ* and *operando* capability, acceleration of scale-up activities using commercial-sized catalysts (e.g., large commercial-size pellets with control over active catalyst distribution in the support), performing process optimization in high-throughput reactors, development of new equipment that can handle harsher reaction feeds and conditions, including high temperature, pressure, corrosive and heavy feeds, improved and faster analytical methods for analyzing reaction products from screening (including analyzing complicated real plant feeds) and for faster/better-characterizing catalyst materials, and further miniaturization and automation.

Abstract

Heterogeneous catalysis is one of the pillars of modern chemical industries. Updated from its previous version published in 2005, the chapter first outlines the general concepts of heterogeneous catalysis and its critical role in chemical processes. It then provides a brief overview of design principles, including kinetics, aspects of adsorption, and microkinetic modeling of heterogeneous catalysts. The chapter then summarizes the representative strategies for catalyst preparation and characterization and the understanding of catalyst deactivation. It finally highlights the future trends in heterogeneous catalysis with an emphasis on sustainable and green chemistry, atomic precision catalysts, and emerging computational design of catalysts.

Key points

- Provides an introduction to fundamental principles of heterogeneous catalysis;
- Covers all aspects of heterogeneous catalytic materials: catalyst preparation, catalyst characterization, and catalyst deactivation;
- Outlines future trends in heterogeneous catalysis development.

Introduction

Catalysis is the process of accelerating the reaction rate by adding a compound known as a catalyst. Catalysts are not consumed in the reaction and remain unchanged after it. A catalyst does not, however, affect the thermodynamics of a reaction or the equilibrium composition of the reaction components (Augustine, 1995; Bowker, 1998; Cornils et al., 2003; Ertl et al., 1999; Farrauto and Bartholomew, 1998; Kamerlin and Warshel, 2010).

Catalysis is the cornerstone of modern chemical industries. More than 90% of the current chemical processes for the production of commodity and fine chemicals involve catalysis. Fig. 1 highlights the use of catalytic transformations to obtain a broad range of

valuable chemicals from C1 gases (CH_4 , CO , and CO_2) (Cui et al., 2019). The C1 sources are obtained from fossil fuels, biomass feedstocks, and organic wastes. Built on well-established catalytic processes, including water-gas shift reaction (WGS), reversed WGS (RWGS), Fischer-Tropsch synthesis (FTS), hydrogenation (HYD), oxidation, oxidative coupling of methane (OCM), and methane dehydroaromatization (MDA), etc., the C1 sources are converted to fuels, olefins, alcohols, and aromatics that are all integral to the modern society (Gates, 1992; Satterfield, 1991; Rase, 2000; Morbidelli et al., 2010; Le Page, 1987; Hagemeyer and Volpe, 2005).

As shown in Fig. 2, three types of catalysts are utilized commercially, including heterogeneous catalysts (porous solids and supported nanoparticles), homogeneous catalysts (dissolved in the liquid reaction mixture), and biological catalysts (enzymes) (Liu and Corma, 2021). Catalytic processes include single-phase homogeneous liquid, two-phase heterogeneous liquid-solid and gas-solid (the most prevalent), and three-phase heterogeneous liquid-solid-gas, implemented using a variety of reactor types. Catalyst activity, selectivity, chemical, and mechanical stability, lifetime, and form determine the cost and the energy efficiency of each process. Control factors to tune catalyst properties are bulk chemical composition, surface composition, stability of active phases, active site structure and distribution, texture (i.e., surface area and porosity), and mass and heat transport. The method of preparation is also crucial to the final catalyst structure and performance (Szostak, 1989).

Catalytic processes are superior to noncatalytic synthetic routes mainly because of energy, raw material savings, and selectivity enhancements. Advantages of heterogeneous catalysis compared to homogeneous catalysis include easy separation of the catalyst and reaction products, minimized reactor corrosion, and larger ranges of possible reaction conditions, which is important when the equilibrium limits the reaction to extreme conditions. Typical heterogeneous catalysts comprise metals or metal oxides and inorganic microporous materials such as zeolites. This chapter is updated from its previous version published in 2005 (Hagemeyer and Volpe, 2005), and focuses on heterogeneous catalysis in the vapor phase.

Fig. 2 Three types of catalysts (bio-, homogeneous, and heterogeneous catalysis).

Applications of catalysis in chemical processes

Thermodynamics frequently limits the concentration of the desired product(s) of a reaction, and conditions (temperature, pressure, space velocity, and reactant composition) must be optimized to maximize the equilibrium concentration of those products. The next step is to develop a catalyst to increase the reaction rate since it is frequently too slow to be practical. It might seem that the optimal catalyst should produce the highest possible reaction rate; however, this is not always the case since such a catalyst might exhibit mass and energy transfer limitations and could be unstable under feasible reaction conditions. The catalyst and the reactor form an integrated unit. Common reactor types (and associated catalyst formulations) are fixed beds (shaped millimeter-sized bodies), fluidized beds (50–150 mm diameter fluidizable particles), stirred tank reactors (slurried powders), and trickle beds (for three-phase reactions). Reactor operation can be continuous, semi-continuous, or batch, with adiabatic or isothermal temperature control. Consideration of mass and energy balance from the macroscopic catalyst bed scale down to the active center is needed to address the complexity of heterogeneous catalysis (Wijngaarden et al., 1998; Twigg, 1989; Thomas and Thomas, 1997).

Status of catalysis research and catalyst discovery

Current approaches used for the understanding and rational design of catalysts include various types of spectroscopies on catalysts and catalyst models, acquisition of kinetic data for catalytic reactions, quantum-chemical and thermodynamic calculations for the elementary steps and molecules involved in a reaction, micro-kinetic modeling, and machine-learning/deep-learning assisted catalyst search and optimization.

Kinetic considerations

The slow step in a reaction mechanism is known as the “rate-limiting step” since it determines the rate of the overall reaction. The rate-limiting step can usually be described as an energy barrier the system must cross. The rate constant has a temperature dependence:

$$k = A \exp(-E_A/RT)$$

where A is the pre-exponential factor and E_A is the activation energy. The activation energy can be determined graphically from the experimental determination of the rate constant as a function of reaction temperature through an Arrhenius plot. A catalyst provides an energetically easier reaction pathway to transform reactants into products that is characterized by lower activation energy.

The kinetics of a catalytic reaction is usually measured in a reactor under relevant process conditions and often power law equations such as $r = C_A^n C_B^m \dots$ that are used to model the macro-kinetics (n , m are reaction orders for A and B).

Aspects of adsorption

Mass transport and adsorption are important aspects of catalysis. Mass transport exists between the fluid phase (gas, liquid) and catalyst particles, and within a catalyst particle. It is important to determine the influence of mass transport on the catalytic reaction rate and product selectivity. The first step in a catalytic event is the adsorption of reactant(s) onto a catalyst surface, followed by chemical reaction(s) at the surface and eventually desorption of products into the fluid phase. There are two main classes of adsorption: physisorption and chemisorption. In physisorption the attractive force is a weak *van der Waals* interaction with an adsorption energy of $\sim 5\text{--}10\text{ kJ mol}^{-1}$ and the chemical bonds in the adsorbing molecules remain intact. Multiple layers of adsorbed molecules are possible. In chemisorption, the adsorption energy is comparable to that of a chemical bond, and the molecule may adsorb intact or it may dissociate. Chemisorption energies are $\sim 30\text{--}70\text{ kJ mol}^{-1}$ for molecules and $\sim 100\text{--}400\text{ kJ mol}^{-1}$ for atoms.

The number of adsorption sites on a catalyst is constant and the competition for those sites has important consequences for macroscopic kinetics and thus catalysis. This is the reason for treating the surface sites as if they were a reactant in the reaction equations. Measurements of adsorption isotherms are used to characterize catalyst porosities and surfaces, to model the reaction kinetics, and help in understanding reaction mechanisms. An isotherm is a coverage considered as a function of temperature and pressure, $\theta(T, p)$. The Brunauer-Emmett-Teller (BET) adsorption isotherm for multi-layer physisorption is used in the determination of catalyst surface areas and porosities. Let the surface area be given by

$$SA = \frac{V_m}{22414} A_m N$$

with SA = surface area, V_m = monolayer volume (cc STP), 22,414 = molar volume of ideal gas (cc STP), A_m = adsorbate molecular cross-sectional area, N = Avogadro's number. The BET model is applied to isotherm data from $P/P_0 = 0.05\text{--}0.35$ as follows:

$$\frac{P/P_0}{V_{ads}(1 - P/P_0)} = \frac{1}{V_m} + \frac{(C - 1)}{V_m C} \frac{P}{P_0}$$

and from the linear relationship, $V_m = 1/(\text{slope} + \text{intercept})$ and $C = \text{slope}/\text{intercept} + 1$ (the C value is related to the heat of adsorption). The Langmuir adsorption isotherm, on the other hand describes adsorption for single-layer chemisorption, i.e., when the adsorbate forms a monolayer with sites having the same adsorption energy. The Langmuir calculation is applicable only to microporous samples:

$$\frac{P/P_0}{V_{ads}} = \frac{1}{V_m B} + \frac{P/P_0}{V_m}$$

and from the linear relationship (typically for $P/P_0 < 0.05$), $V_m = 1/\text{slope}$.

Catalysis

In a catalytic reaction, active sites react and are regenerated and reused in a cyclic manner. The catalyst activity depends on “the number of active sites” and “the turnover frequency.” The reaction mechanism consists of many different steps each of which may be of a different type. For example, the Langmuir-Hinshelwood mechanism consists of the following sequence of steps: (1) adsorption from the gas phase, (2) dissociation of molecules at the surface, (3) reactions between adsorbed molecules, and (4) desorption to the gas phase. The Eley-Rideal mechanism covers another important class of reactions and consists of: (1) adsorption from the gas phase, (2) dissociation of molecules at the surface, (3) reactions between gas and adsorbed molecules, and (4) desorption to the gas phase. The Mars-van Krevelen mechanism is often observed for selective oxidations over reducible metal oxide catalysts when lattice oxygen from the oxide is inserted into the hydrocarbon reactant and the lattice defect is subsequently re-oxidized by reaction with gaseous oxygen. The oxidation of the hydrocarbon is thus mediated by the catalyst which is the direct oxidizing agent providing nucleophilic lattice oxygen that is often more selective than molecular or chemisorbed oxygen species.

The principle of Sabatier

An ideal catalyst should bind products and reactants with a moderate strength: neither too strongly to desorb the products nor too weakly to activate the reactants. This leads to a volcano curve of the rate versus adsorption as illustrated in Fig. 3A, which is known as the “Principle of Sabatier” (Medford et al., 2015). In general, the activation energy for the catalyzed dissociation of diatomic molecules decreases when moving left from the noble metals in the periodic table. For example, taking CO as a simple model for adsorption, the *anti*-bonding $2\pi^*$ states are partially filled when chemisorbed and they fill further during dissociation. The *anti*-bonding molecular states must be close to the Fermi level of the metal, and when the metal has *d*-states close to the Fermi level, as in the transition metals, there is a strong covalent interaction between the *anti*-bonding states and the metal *d*-states. For the early transition metals with low *d* filling, the *anti*-bonding metal-C orbital is almost empty due to strong donation resulting in a stronger metal-CO bond, negative adsorption enthalpy, and dissociation (e.g., Fischer Tropsch metals Fe, Co, and Ru), whereas for

Fig. 3 (A) Schematic representation of the qualitative Sabatier principle (Medford et al., 2015). (B) Computationally established Sabatier principle for ammonia synthesis activity on the step sites of different transition metals (Xu et al., 2022). (A) From Medford AJ, Vojvodic A, Hummelshøj JS, Voss J, Abild-Pedersen F et al. (2015) From the Sabatier principle to a predictive theory of transition-metal heterogeneous catalysis. *Journal of Catalysis* 328: 36–42. Copyright 2015, Elsevier. (B) From Xu G, Cai C, and Wang T (2022) Toward sabatier optimal for ammonia synthesis with paramagnetic phase of ferromagnetic transition metal catalysts. *Journal of the American Chemical Society* 144: 23089–23095. Copyright 2022, ACS.

the late transition metals and noble metals with high *d* filling, the *anti*-bonding metal-C orbital is almost full due to strong back-donation resulting in weaker metal-CO bond, positive adsorption enthalpy, and no dissociation.

The Haber-Bosch process, converting hydrogen (H₂) and nitrogen (N₂) to ammonia (NH₃), is an important reaction in heterogeneous catalysis. In order to guide the new catalyst design, the volcano plot between nitrogen binding energy and ammonia synthesis activity among metals has been established. As shown in Fig. 3B, the activities of metals with low nitrogen binding energy are limited by the hydrogenation steps (the left), and those with high nitrogen binding energy will be hindered by the high transition state energy of N₂ dissociation (the right) (Xu et al., 2022). Therefore, the catalyst with a moderate nitrogen binding energy and small transition state energy of N₂ dissociation denotes the Sabatier optimal for the Haber-Bosch process. Additionally, Fig. 3B reveals that the TOF on the same catalytically active site, such as Fe, Co, and Ni metals, strongly depends on their metallic element.

Microkinetic modeling

The detailed microscopic description of a chemical reaction in terms of the motion of the individual atoms taking part in the event is known as the “reaction dynamics.” The link between the microscopic description of the reaction dynamics and the macroscopic kinetics that can be measured in a catalytic reactor is the micro-kinetic model. Such a model for a given reaction begins with binding energies and reaction rate constants deduced from surface science experiments on well-defined single-crystal surfaces and relates these to the macroscopic kinetics of the reaction. The aim is to identify the basic parameters of the reactants and the surface that determine the reaction dynamics (activation barriers, etc.) and relate them to factors determining the catalytic activity. The models are useful for understanding variations in the catalytic activity from one system to another. The stability of the intermediates and the activation barriers are among the input parameters for the micro-kinetic model, and it is straightforward to calculate the effects of changes in stability for some or all the intermediates.

Catalyst properties, shapes, and preparation

Catalysts for continuous-flow fix-bed processes must be shaped to allow the fluid reactant stream to freely pass through the packed bed with an acceptable pressure drop and come into contact with a surface area as large as possible. An example is illustrated in Fig. 4 where catalyst bodies of various sizes, shapes, and geometries (e.g., powder, 10-hole ring, multicore-shell, monolith, foam, core-shell and pellet) are used for biogas reforming. The shape determines the void fraction, packing density, and mechanical strength (Zhao et al., 2020). The fluid mechanics, flow characteristics and pressure drop, and diffusion restrictions are influenced by the shape and size of the catalyst bodies. Small bodies are often easier to manufacture but suffer from higher pressure drop.

Catalyst pellets used in commercial fixed-bed reactors range in diameter from 1.5 to 10 mm. Typical ring sizes are 6–20 mm. Extrudates are 1–5 mm in diameter and 10–30 mm long. Pellets can have several channels and are usually 20–40 mm in diameter and 10–20 mm long (compared to a ring, the use of several smaller channels gives improved mechanical strength with good mass- and heat-transport). Monoliths are used for high gas flow rates or dust (fly ash, soot) containing gas feeds. For the control of emissions in power plant exhaust gas streams, for instance, typical honeycombs are sized 150 mm in edge and 1 m in length,

Fig. 4 Catalysts of various shapes are used in biogas reforming. Biogas is produced from the digestion process that breaks organic matter (e.g., wastewater). Through the reforming process, biogas gas can be converted to syngas (CO and H₂), which can be subsequently used to synthesize other chemicals (Zhao et al., 2020). From Zhao X, Joseph B, Kuhn J, and Ozcan S (2020) Biogas reforming to syngas: A review. *iScience* 23: 101082. Copyright 2020, Elsevier.

with ~1000 channels per monolith. A stack consists of two to three layers of several hundred honeycombs each. Solid catalysts can be entirely composed of the catalytically active material (bulk catalysts) or supported on porous carriers to improve the mechanical stability or finely distribute the active material thereby creating a large number of active sites.

High activity and selectivity, long-term stability (lifetime), resistance to poisons, tolerance to deviations from operating conditions such as temperature excursions (hot spots), good mechanical strength, and lack of toxic or hazardous ingredients make high demands on technical catalysts. A variety of synthetic tools are available for the preparation of catalysts, and the performance often more strongly depends on the details of the synthetic route rather than the final composition.

Precipitation (bulk catalysts)

Catalysts are precipitated by mixing one solution with another solution or a suspension to form an insoluble compound. Typical precipitation agents are acids or bases to induce a pH change to a metal salt solution. The precipitate is filtered, washed, dried, calcined, and crushed to a fine powder. A binder is added, and the powder is tableted. The catalyst may also be shaped before calcination by extruding the filter cake. Typical binders are graphite or stearic acid. Common catalysts prepared by precipitation include alumina-supported Cu-Zn for methanol synthesis and the water gas shift reaction.

Fusion (bulk, pre-molten alloys, and metal oxides)

Catalysts based on metals and metal oxides may be prepared by fusion, crushing, and screening. The finished catalyst consists of irregular pieces of a narrow range of sizes. Fusion is only possible for catalysts that are conductors at high temperatures. During the preparative process, the catalyst powder is placed in an electro-furnace and heated by passing a large current through graphite electrodes. At the start of the cycle, a solid catalyst is added to the furnace and the electrodes are lowered. The voltage is fixed, and the current is regulated through the height of the electrodes. The molten mass is stirred by the electromagnetic fields generated by the current flowing between the electrodes. At the end of the process, the electrodes are raised, and the molten catalyst is poured out.

The catalyst has no porosity before reduction. The pore system is created when the metal oxide is reduced during the activation of the catalyst (the catalyst may also be supplied in pre-reduced form). The pre-reduced catalyst is first completely reduced then passivated by gentle oxidation to allow it to be transported and loaded safely. Common catalysts prepared by fusion include alloy catalysts (e.g., Pt-Rh gauze for ammonia oxidation) and oxides (e.g., Fe oxide for ammonia synthesis or Fischer-Tropsch synthesis), and fused V₂O₅-K₂S₂O₇ for sulfuric acid synthesis.

Evaporative methods

Wet mixing of (soluble or insoluble) metal precursors in water or organic solvents and subsequent removal of the solvent by evaporation, freeze drying, or spray drying may be used to produce mixed multi-metal oxide catalysts. Often, preformed catalyst powders are slurried and spray-dried once again to produce a fluffy and compactable powder for subsequent shaping by extrusion or tablet pressing.

Impregnation (supported catalysts)

Impregnated catalysts are prepared by impregnating (e.g., spraying) a solution of a metal salt or mixture onto pellets of a porous support. The metal loading in the finished catalyst is typically 1–5% but can be as low as 0.1%. When liquid is slowly added to a porous solid powder, the liquid is first absorbed in the pores and the powder flows as if it is dry. When the pores are filled, the outer surface of the granules suddenly becomes wet, the granules tend to stick together, and the powder forms lump instead of flowing freely. Incipient wetness is the point when the pores are filled, but the outer surface of the granules is dry, and can easily be determined by shaking or stirring the powder. Following impregnation to incipient wetness, the pellets are dried and calcined to transform the metal into an insoluble form. The metal salt can be deposited homogeneously through the pellet or most of the metal may be deposited near the outside of the pellet. The distribution of the metal is controlled through the interaction of the metal solution(s) with the support, e.g., through varying the metal counterion, through control of pH, or through the addition of chelating agents to the impregnation liquid. The impregnation method (wet versus dry, fast, and slow) and drying conditions can also affect distribution. Typical distributions include eggshell, egg white, and egg yolk. Shell catalysts are often used for selective oxidations to overcome pore diffusion limitations and suppress consecutive over-oxidation reactions, whereas egg-white catalysts are used in refining to protect the inner catalyst layer from feed poisons.

Compared to other catalyst preparation methods, impregnation offers several advantages. For example, the pellets may be shaped before the metal is added; the filtering and washing of the catalysts are not necessary; low metal loadings are easily achieved; and control over the distribution of the metal in pellets is possible.

Common catalysts prepared by impregnation include carbon-supported Pt and Pd for hydrogenations, ceria-zirconia supported Pt-Rh for the three-way catalytic converter, and titania-supported V_2O_5 for NO_x abatement.

Catalyst supports

Since the catalysis occurs at the surface of the metal particles, the catalysts are prepared so as to expose a large metal area, typically $10\text{--}100\text{ m}^2\text{ g}^{-1}$ of catalyst. The function of the support is primarily to increase and stabilize the area of the metal particles. The size of the metal particles may be reported as the total area of the metal surface, as the diameter of the metal particles (commonly 3–15 nm), and as the so-called metal dispersion (defined as the fraction of all metal atoms that are present at the metal particle surface, commonly from 20 up to ~80%).

Support contains pores having irregular shapes. These pores fall into two size ranges. Macro-pores have diameters of 100 nm or more and are formed from cracks/spaces between crystallites. Micro-pores have diameters of 1 nm or less and are due to the “roughness” of the solid surface itself, or the structure of the crystal lattice.

Hydrothermal synthesis (zeolites)

Typically, Si and Al precursors together with an organic structure-directing agent are heated up to 200 °C under autogenous pressure in autoclaves for up to several days to synthesize crystalline microporous zeolites or other molecular sieves such as aluminophosphates. These materials have well-defined pore structures (pore diameters ranging from ~3 to 8 Å) as compared to the broad pore size distributions found in traditional carrier materials. As catalysts, they may contain metal in the pore. Applications of zeolites as supports, solid acids or shape-selective catalysis are common. Zeolites are widely used in refining and petrochemicals, e.g., ultra-stabilized Y zeolite for fluid catalytic cracking and ZSM-5 for xylene isomerization.

Raney metals

Highly porous metal sponges can be made in aqueous solutions by the dissolution of aluminum alloys using a strong base. Metal sponges are typically used for hydrogenation in laboratory synthesis. Raney nickel is made by dissolving an (Al, Ni)-alloy containing 50% Ni in 20% NaOH in water. The surface area is $80\text{--}100\text{ m}^2\text{ g}^{-1}$. The most commonly used Raney metals are Ni, Co, Cu, and Fe.

Colloidal wet-chemical synthesis

Colloidal nanoparticles and clusters (1–20 nm) can be prepared by chemical reduction or decomposition of metal compounds in solution in the presence of surfactants or stabilizing polymers (Lee et al., 2013). The synthesized nanoparticles and clusters can be adsorbed onto high-surface-area supports (metal oxide or carbon) as the supported catalysts. A significant advantage of colloidal wet-chemical synthesis is the possibility to tune the nanoparticle physical dimensions (sizes and shapes), compositions

(alloys or doping), atomic structures (crystal phases), and architectures (heterostructures, core/shell), which has been extensively studied in past two decades and demonstrated substantial success for metals and metal oxides nanocatalysts (Zhang et al., 2014, 2019; Wu et al., 2018; Shi et al., 2021). Once loaded onto supports, colloidal nanocatalysts are often surface activated by removing surfactants, as the surfactants may block the active surface for catalysis. The typical ligand removal methods include thermal calcination, UV-ozone cleaning, and ligand exchange and stripping (Dong et al., 2011; Luo et al., 2017; Cargnello et al., 2015; Li et al., 2012; Godbold et al., 2021).

Nanocatalysts produced through colloidal wet-chemical synthesis could present uniform size and structure (also called monodisperse nanoparticles or well-defined nanoparticles) and thus are beneficial to unambiguously understand the structure-property relationship in catalysis, which is unachievable by using ill-defined catalysts synthesized in other methods (Yan et al., 2018; Qin et al., 2018, 2020; Mitchell et al., 2021). Fig. 5A displays High-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) image of an ill-defined Fe oxide-supported Au catalyst, revealing the existence of small clusters and

Copyright 2021, Springer Nature.

individual atoms in addition to nanoparticles (Mitchell et al., 2021; Allard et al., 2009). Using colloidal synthesis, well-defined nanoparticles can be created with controllable sizes and shapes (exposed surface facets), as illustrated in Fig. 5B and C (Cargnello et al., 2013). Besides nanoparticles loaded on metal oxide supports, colloidal synthesis also enables to generate inversed structure by modifying the nanoparticle surface with active metal oxide coverage (Fig. 5D) (Chen et al., 2014). The new opportunities presented by colloidal synthesis are built on the ability and the ease of modulating nanoparticle nucleation and growth kinetics in solution phase by tailoring reaction conditions and using functional surfactant ligands. As shown in Fig. 5E–G, this wet-chemical strategy has been expanded to synthesize well-defined cluster catalysts, confined active sites in porous zeolite/Metal Organic Framework (MOF), and single-atom catalysts (Liu et al., 2017, 2016; Wang et al., 2016).

Catalyst characterization

Catalysts are characterized for chemical composition, atomic order (crystallinity), phase identification and distribution, porosity, and to identify deactivation mechanisms. Commonly applied techniques include inductively coupled plasma, X-ray fluorescence, physisorption measurements (BET, Hg porosimetry, various titration techniques), electron microscopy (SEM, TEM, and STEM), Auger spectroscopy, X-ray photoelectron spectroscopy, atomic force microscopy, secondary ion mass spectrometry, X-ray absorption, and X-ray diffraction. These methods are often combined to provide a more detailed analysis of the catalyst structures and physical and chemical properties. Over the past decades, *in-situ* and *operando* characterizations have been extensively pursued to reveal the reaction mechanism and the real active site structures and energetics during catalytic processes (Wu et al., 2018; Tsoukalou et al., 2019; Kovtunov et al., 2019; Beck et al., 2021).

Catalyst deactivation

A number of different processes that contribute to the loss of catalyst activity with time on stream are described below. This problem is most often dealt with commercially by slowly increasing the catalyst temperature over time to maintain constant activity/productivity. When it is no longer possible to achieve the necessary performance, the catalyst is replaced (Lin et al., 2021).

Sintering

For supported metal catalysts, the active component is present on the catalyst in the form of small particles which are inherently unstable. A catalyst slowly loses activity due to the growth of these particles (favored by the resulting decrease in surface energy) and the resulting loss of surface area. There are two mechanisms for sintering: atoms may detach from one particle and move to another (Ostwald ripening), or crystallites may move along the support surface and coalesce. Sintering depends on the nature of the metal, the support, the strength of the metal-support interaction, the gases present, temperature, pressure, and time. Catalyst sintering is irreversible.

Structure decomposition or structure collapse

Crystalline catalysts such as zeolites and multi-metal oxides can deactivate due to the destruction of the crystalline phase or lattice structure. Another problem can be the loss of elements from the catalyst (or volatile compounds such as Mo, Re, etc.). This can be solved in some cases by the slow addition of the volatile element to the catalyst bed. In the case of attrition losses (e.g., for fluid catalytic cracking (FCC) zeolite catalysts), it is necessary to add in new catalysts slowly over time to the riser.

Fouling and poisoning

Catalytic activity may also be lost due to the formation of carbon ("coking") or due to the deposition of impurities or of dust or other particulates in the reactant stream onto the catalyst surface. The formation of carbon in many cases is reversible. For example, the catalyst can be taken offline, and the carbon removed by oxidation ("catalyst regeneration").

Examples of fouling by particulates occur in the removal of NO_x from industrial flue gases or in catalytic converters used in automobiles. In these cases, the catalyst is manufactured in a shape that allows the particulates to pass through the reactor with minimum accumulation (e.g., a catalyst was coated onto a ceramic monolith). A serious problem with catalyst dust may occur if the catalyst bed is improperly loaded, if there is a problem with excessive vibration in the reactor, or if physically weak catalysts are used. In these cases, dust may be formed by attrition, leading to dust accumulation in the reactor or elsewhere in the process impeding or blocking the gas flow. The highly reactive catalyst dust presents a serious safety hazard since it can cause an explosion when pipes or heat exchangers are opened for maintenance.

Examples of poisons that can be present in feeds include metallic impurities such as V, Na, and Ni in FCC processes, metallo-organics in desulfurization processes, and thiophenic sulfur compounds in various refining processes such as reforming. These poisons react with the catalyst and reduce or destroy its activity. It is often necessary to remove the poisons with a guard bed or dedicated upstream catalytic process (as is done with hydrosulfurization, for example). Sometimes, the impurity is completely absorbed in the first few percent of the catalyst bed due to its strong interaction with the catalyst.

Conclusion

Commercial catalysts are used in refining (e.g., alkylation, dimerization, disproportionation, isomerization, catalytic cracking, FCC, hydro-processing (e.g., hydrotreating, hydrodesulfurization, hydrocracking), hydrogen production, reforming), chemical catalysis (e.g., aromatics production, monomer synthesis, polymerization, organic synthesis, cyclic and acyclic intermediates, medical, flavors and perfumes, rubber processing, plasticizers, surface active agents, agricultural, using oxidation, hydrogenation, dehydrogenation, phase transfer catalysis), biocatalysis, and environmental applications (automobile and industrial pollution control). There are numerous references available covering these applications in detail. The competitive pressures of a mature industry, the trend toward simpler and less capital-intensive processes, access to cheaper and renewable feedstocks, and the desire for more environmentally benign processes drive the development of new, high-performance catalysts in the future. Meanwhile, the demand for sustainable energy and green chemistry requires to shift conventional thermal catalytic processes to electrocatalytic or photocatalytic processes that can effectively utilize renewable electrical and solar energies. This also leads to tremendous efforts in developing emerging materials that are suited to these new catalytic processes (e.g., electrocatalysts for water splitting to produce clean H_2 , electrocatalysts for CO_2 reduction to CO, formate, methanol etc.) (Godbold et al., 2021; Yin et al., 2022; Zhang et al., 2018; Liu et al., 2020).

The design and construction of atomically precise catalytic sites will continue to be at the forefront of catalysis research and development. Colloidal synthesis of well-defined nanoparticles and cluster catalysts is a representative example. New opportunities also exist in the development of heterogeneous catalysts through the controlled assembly of functional building blocks (Sudarsanam et al., 2019; Bennett et al., 2021). As shown in Fig. 6, diverse assembling building units, covering both inorganic and organic units, have long been applied in a variety of catalytic applications, and their porosities and topological structures can greatly determine the reaction mechanisms, accessibility of specific active sites and the selectivity of target products (Bennett et al., 2021). New approaches to the discovery of potentially new catalytic hybrid materials, including innovative preparation methods and combinatorial/high-throughput catalysis, are having positive impacts on catalyst development.

Although catalysis has been used in industry for more than 150 years, the experimental techniques for investigating catalysis at the atomic level did not become routine until about 25 years ago, and the computational techniques not until 10 years ago. For this reason, the field has still been largely an empirical one. Fig. 7 highlights the complexity of the catalytic process at the scales ranging from atomic transformation at the catalyst surface to the complicated macroscale environment (heat, mass, and potential), which requires the rapid development of quantum mechanics and multiscale computational methods to further deepen the understanding of reaction mechanisms and catalyst designing principles (Bruix et al., 2019). The continued development of the computational method, especially emerging machine learning (ML) and artificial intelligence (AI)-guided catalyst design, will open new or additional opportunities in search of high-performance catalysts with complex multi-element compositions and structures that are impossible through conventional empirical strategies.

Introduction

When the solution of a mathematical problem cannot be obtained in an analytical form (e.g., the solution of a differential equation) or when it requires too many arithmetical operations (as the solution of a system of linear equations by Cramer's rule), then it is necessary to make use of a numerical method. Usually, such a method only provides an approximation of the solution. Numerical analysis is the branch of mathematics where constructive methods (that is methods able to construct effectively, numerically, the solution) are defined and studied.

Numerical approximation covers the approximation of functions in various senses (interpolation, best approximation, Padé approximation, etc.), the numerical solution of differential and integral equations, the computation of definite integrals, the solution of systems of linear and nonlinear equations, the computation of eigenelements, etc. It is beyond the scope of this article to enter into details and the aim of the article is to give a flavor of the domain and to describe the main ideas.

A numerical method is implemented on a computer. So, each arithmetical operation is affected by an error since computers work with numbers having a finite number of digits. So, the result which is finally obtained depends not only on the quality of the approximation used but also on the propagation of these rounding errors. Taking this point into account is fundamental when using a numerical method.

Approximation of Functions

In many situations, one needs to approximate a function f by another function g . The procedure to be used depends highly on the information on f and on the form of g . The function g can be a polynomial or a combination of given functions satisfying some conditions, or a rational function, or a spline (piecewise polynomials). If f is known at some given points x_i , then interpolation can be used. Interpolation determines the unknown parameters involved in g and provides approximations $g(x_i)$ of $f(x_i)$. If the numbers of parameters are less than the numbers of interpolation points, f can be approximated in the least squares sense. If the information on f is analytic, approximation in the sense of some norm can be used.

If the Taylor expansion of f around zero is known, a quite powerful procedure is Padé approximation. It is assumed that the formal expansion

$$f(z) = c_0 + c_1 z + c_2 z^2 + \dots$$

is known. A rational approximation is derived with a numerator $N_p(z) = a_0 + \dots + a_p z^p$ and a denominator $D_q(z) = b_0 + \dots + b_q z^q$ so that the series expansion of $N_p(z)/D_q(z)$ agrees with the expansion of f as far as possible, which means

$$f(z)D_q(z) - N_p(z) = \mathcal{O}(z^{p+q+1})$$

Such a rational function is called a Padé approximant and it is denoted by $[p/q]_f(z)$. The coefficients of N_p and D_q given by

$$\begin{aligned} a_0 &= b_0 c_0 \\ a_1 &= b_0 c_1 + b_1 c_0 \\ &\vdots \\ a_p &= b_0 c_p + \dots + b_q c_{p-q} \\ 0 &= b_0 c_{p+1} + \dots + b_q c_{p-q+1} \\ &\vdots \\ 0 &= b_0 c_{p+q} + \dots + b_q c_p a_0 \end{aligned}$$

with $c_i=0$ for $i<0$. Setting $b_0=1$ and solving the system formed by the last q equations gives the b_i . Then the a_i are directly obtained by the first p relations.

Padé approximants are widely used in many problems of mathematical physics.

Ordinary Differential Equations

Consider a Cauchy problem for a system of k ordinary differential equations

$$\begin{aligned} y'(x) &= f(x, y(x)), \quad x \in [a, b] \\ y(a) &= y_0 \end{aligned}$$

where $f: \mathbb{R} \times \mathbb{R}^k \rightarrow \mathbb{R}^k$, $y \in \mathbb{R}^k$, and $y_0 \in \mathbb{R}^k$ is given.

A numerical method for the integration of this system consists in constructing approximations y_n of the exact solution $y(x_n)$ at some chosen points $a = x_0 < x_1 < \dots < x_n < \dots < x_N = b$ in the interval of integration. There are two types of procedures for obtaining these approximations: one-step methods (where y_{n+1} is deduced only from y_n) and multistep methods (where y_{n+1} depends on $y_n, \dots, y_{n-p}$).

First choose a fixed step size $h(b-a)/N$ and set $x_n = a + nh$ for $n = 0, \dots, N$. Of course, for $y_0, \dots, y_N$ to be approximations of $y(x_0), \dots, y(x_N)$, the formula for computing y_{n+1} has to satisfy some properties, namely the consistency, the stability, and the convergence which means that the error tends to zero when h tends to zero. Another quite important property of a method is its order r which explains the behavior of the error with h , $y_n - y(x_n) = O(h^r)$.

In a one-step method, the approximate solution is computed by

$$y_{n+1} = y_n + h\Phi(x_n, y_n, h), \quad n = 0, \dots, N-1$$

A Runge-Kutta method consists in

$$\begin{aligned} k_i &= f(x_n + \theta_i h, y_n + h\eta_i) \\ \eta_i &= a_{i1}k_1 + \dots + a_{im}k_m \\ \Phi(x_n, y_n, h) &= c_1k_1 + \dots + c_mk_m \end{aligned}$$

If $a_{ij}=0$ for $j \geq i$, the method is explicit (which means that each k_i can be computed separately) while, if not, it is implicit and the k_i are given as the solution of a system of (nonlinear) equations. Of course, an implicit method is much more difficult to implement but, in the case of a stiff differential equation (that is an equation whose solution varies rapidly), such an implicit method has to be used.

In a multistep method, $y_0, \dots, y_{p-1}$ have first to be computed by a one-step method and then $y_p, \dots, y_N$ are obtained by

$$a_0y_n + \dots + a_p y_{n+p} = h(b_0f_n + \dots + b_p f_{n+p})$$

for $n=0, \dots, N-p$, where $f_i = f(x_i, y_i)$. If $b_p=0$ the method is explicit, otherwise it is implicit.

The main practical problem about the numerical integration of a differential equation concerns the precision of the approximate solution. If a desired precision has to be achieved, the first step is to choose the method. Then, h has to be chosen and adapted along the interval of integration in order to obtain the desired accuracy. This means, of course, that a procedure for estimating the error has to be implemented.

Integral Equations

Let g and K be two known functions. There are two kinds of integral equations depending whether the unknown function f appears only under the integral sign or also outside it. In these two kinds, two types arise depending on the interval of integration. If the interval of integration has fixed endpoints, a Fredholm equation is obtained.

$$\begin{aligned} \text{1st kind : } & \int_a^b K(x, t)f(t)dt = g(x) \\ \text{2nd kind : } & f(x) - \lambda \int_a^b K(x, t)f(t)dt = g(x) \end{aligned}$$

where $\lambda \neq 0$ is a parameter. If the right endpoint is a variable, a Volterra equation is obtained.

$$\begin{aligned} \text{1st kind : } & \int_a^x K(x, t)f(t)dt = g(x) \\ \text{2nd kind : } & f(x) - \lambda \int_a^x K(x, t)f(t)dt = g(x) \end{aligned}$$

Fredholm equations reduce to Volterra if the kernel K is such that $K(x, t)=0$ for $x \leq t \leq b$.

To obtain approximations f_j of the function f at some points x_j , assume that the function g is known at some points x_i . So

$$g(x_i) = \int_a^b K(x_i, t)f(t)dt, i = 1, \dots, N$$

and similarly for the other integral equations. The definite integral is evaluated by a quadrature formula

$$\int_a^b K(x_i, t)f(t)dt \simeq \sum_{j=1}^M a_{ij}f(t_j)$$

Thus, the approximations $f_j \simeq f(t_j)$ is obtained by solving the system of linear equations

$$g(x_i) = \sum_{j=1}^M a_{ij}f_j, i = 1, \dots, N$$

If $N \neq M$, the system is solved in the least squares sense. Otherwise, a square system is obtained. However, it must be noticed that this system is usually ill-conditioned and thus preconditioning and/or regularization have to be used (see the next section). This is the case with the inversion of the Laplace transform, one of the most important integral equations.

Fredholm equations of the second kind can be solved by the method of successive approximations. If $\mathcal{K}$ denotes the integral operator which maps f into $\int_a^b K(x, t)f(t)$, then this integral equation is $(I - \lambda\mathcal{K})f = g$. So, f is given by its Neumann series

$$f = (I - \lambda\mathcal{K})^{-1}g = I + \sum_{i=0}^{\infty} \lambda^i \mathcal{K}^i g$$

In other terms, set $f_0 = g$ and then compute

$$f_i(x) = g(x) + \lambda \int_a^b K(x, t)f_{i-1}(t)dt, i = 1, 2, \dots$$

This method converges if $\|\lambda\mathcal{K}\| > 1$.

Systems of Linear Equations

The choice of a method for solving a system of p linear equations in p unknowns, $Ax=b$, highly depends on the value of p . There are two classes of methods: direct methods and iterative methods.

When p is not too large (i.e., up to 10^4), an elimination procedure, such as Gaussian elimination, or Cholesky decomposition if the matrix is symmetric and positive definite, or Householder factorization, can be used. They all consist in transforming the system into an equivalent one (i.e., with the same solution) but with a matrix which is upper triangular. Then, such a system can be easily solved starting from the last equation.

When p is very large (several millions) and the matrix of the system comes out from the discretization, by finite differences or finite elements, of a partial differential equation, it is sparse (which means that most elements are zero). However, a direct method could not be used since the upper triangular matrix obtained by a direct method could be full. In that case, iterative methods are preferred. These methods split into two subclasses: relaxation methods and projection methods. Relaxation methods are nowadays mostly used as preconditioners (see below). Projection methods consist in generating a sequence of approximate solutions belonging to subspaces of increasing dimensions. Usually, these subspaces are Krylov subspaces and thus the name of such methods. Among them, the most popular are Lanczos method, the BiCGStab, and GMRES.

A fundamental topic of the solution of a system of linear equations is the condition number $\kappa(A) = \|A\| \cdot \|A^{-1}\|$ of the matrix A , a number greater than 1. If this number is large, then a small perturbation of the matrix A and/or the right-hand side b can produce a large variation in the exact solution of the system. The system is said to be ill-conditioned. Also, the speed of convergence of some Krylov subspace methods depends on the condition number: the larger it is the slower is the convergence. Thus, it is important, when a matrix is ill-conditioned to precondition the system, that is to consider the new system $M^{-1}Ax = M^{-1}b$, where the matrix M is an approximation of A easy to invert (or, equivalently, a system with M as its matrix is easy to solve) and chosen so that $\kappa(M^{-1}A)$ is smaller than $\kappa(A)$. There is no universal preconditioner and almost each system is a particular case.

Another procedure for solving an ill-conditioned system is to use regularization. It consists in solving a perturbed system. A vector x which minimizes

$$\|Ax - b\|_2 + \lambda \|Hx\|$$

is derived where λ is a parameter and H a matrix. The solution x_λ depends on $\lambda \geq 0$ (and also on H). When λ is close to 0, x_λ is close to $x = A^{-1}b$ but, since A is ill-conditioned, it is badly computed. If λ is large, x_λ will be correctly computed but it will not be a good approximation of x . So, there is a balance to find between large and small values of λ , and this is the main difficulty of regularization. It can be avoided by using an extrapolation technique.

Introduction

Computer simulation techniques in condensed matter physics aim to compute the structure and the physical properties (including also dynamic response functions and transport) from atomistic input. The theoretical basis of these approaches are quantum mechanics and statistical thermodynamics. There exist many variants of these methods, and it depends on the nature of the problem to find out which variant is most appropriate. Such simulations can complement both analytical theory and experiment, and due to the availability of cheap computing power simulations have become an extremely widespread tool of research.

The conceptually simplest approach is the classical molecular dynamics (MD) method: one simply solves Newton's equations of motion numerically for the many-particle system (assuming that the N atoms or molecules in a volume V interact with effective potentials that are either phenomenologically assumed or fitted to electronic structure calculations). The basis of this method thus is classical mechanics, and one creates a deterministic trajectory in the phase space of the system. The idea is to take time averages of the observables of interest along this trajectory. The ergodicity hypothesis of statistical mechanics asserts that these time averages are equivalent to ensemble averages of the appropriate microcanonical (NVE) ensemble. Of course, Newton's equations of motion conserve the total energy E , and hence the conjugate intensive thermodynamic variables (temperature T , pressure p) can only be indirectly inferred and they exhibit statistical fluctuations. Since N is finite and sometimes even fairly small, such fluctuations cannot be neglected and need to be considered with care.

Sometimes one desires to directly realize other ensembles of statistical mechanics with a simulation, for example, the NVT or NpT ensemble. This is possible by introducing a coupling to suitable "thermostats" or "barostats."

An alternative way to carry out an MD simulation with $T = \text{const}$ introduces a weak friction force, together with random forces whose strengths are controlled by the fluctuation dissipation theorem. This method is closely related to the "Brownian Dynamics" (BD) method where one simulates Langevin equations (the inertial terms in the equations of motion being omitted). Clearly, this is a coarse-grained description of a physical system as only a subset of the degrees of freedom is explicitly considered, the remaining ones form the "heat bath." While this is not always a good description of the physical dynamics, such methods can be advantageous for the computation of static properties from averages along the stochastic trajectory in phase space.

A similar description applies to the importance sampling Monte Carlo (MC) method, where one creates a random walk-like trajectory in configuration space, controlled by transition probabilities that ensure the approach to thermal equilibrium through the detailed balance condition. Many of the practical limitations of simulations, such as "statistical errors," as well as systematic errors due to the finite size of the simulated system or the finite "length" of the simulated trajectory (or observation time, respectively) are common to all these simulation methods.

Of course, it is quantum mechanics and not classical mechanics that describes the basic physics of condensed matter. But attempting a numerical solution of the Schrödinger equation for a system of many nuclei and electrons is premature and still not feasible even with the fastest computers. Thus, approximations are needed: one very popular approach is the "ab initio MD" or "Car-Parrinello method" (CP), where some electronic degrees of freedom are included in MD via the density-functional theory (DFT). The huge advantage of this technique is that one no longer relies on effective interatomic potentials, which often are only phenomenologically chosen *ad hoc* assumptions, lacking any firm foundation in quantum chemistry. However, the disadvantage of this technique is that it is several orders of magnitude slower than classical MD, and hence only very short timescales and very small systems are accessible. Furthermore, the method cannot handle van der Waals-like forces well (e.g., in noble gases, one is still better off with the simple Lennard-Jones potential, amended by three-body forces).

In the standard CP method, the ionic motion is still treated classically. Alternatively, one can still use effective potentials between ions and/or neutral atoms as in classical MD or MC, but rely on quantum statistical mechanics for the ionic degrees of freedom. This is achieved by the path integral Monte Carlo (PIMC) or path integral molecular dynamics (PIMD). Such techniques are indeed crucial for a study of solids at low temperatures, to ensure that their thermal properties are compatible with the third law of thermodynamics. For most fluids, however, classical MD is sufficient (of course, quantum liquids such as helium are an exception).

Other variants of quantum Monte Carlo (QMC) have been developed in order to deal with electronic degrees of freedom on rigid lattices, desiring to describe magnetic systems (e.g., via the Heisenberg model where spin operators at neighboring lattice sites

are coupled by exchange interactions), models for high T_c superconductors (e.g., using the Hubbard Hamiltonian, describing a hopping of electrons from site to site, and an on-site Coulomb repulsion), etc. These techniques ("diffusion Monte Carlo," "Green's function Monte Carlo," "variational Monte Carlo," "worldline Monte Carlo," etc.) are fairly specialized and complicated, and hence are not treated further here.

What information does one then wish to extract from the simulations? When systems in thermal equilibrium are considered, the first task is to calculate static properties. For example, in a fluid a basic property is the static structure factor $S(k)$, $S(k) = \langle |\delta\rho(\mathbf{k})|^2 \rangle_T$, $\delta\rho(\mathbf{k})$ being a spatial Fourier transform of density fluctuations, $\mathbf{k}$ being the wave vector of a scattering experiment. In addition, one may want to calculate time-dependent correlation functions that describe the decay of small thermal fluctuations in equilibrium systems with time. A quantity of this type is the intermediate scattering function $S(k, t) = \langle \delta\rho(-\mathbf{k}, 0) \delta\rho(\mathbf{k}, t) \rangle$ or its Fourier transform with respect to time, $S(k, \omega)$. This "dynamic structure factor" is accessible to inelastic scattering of neutrons, X-rays, or light (with energy transfer $\hbar\omega$).

It is also possible to consider systems out of thermal equilibrium; for example, in solids under strong mechanical deformation, a crack may form and propagate. An important application of MD for fluids also is the study of systems exhibiting a steady state flow under shear deformation. The purpose of such nonequilibrium molecular dynamics (NEMD) work can be the estimation of transport coefficients (e.g., the shear viscosity) if the deformation is weak enough so that the system is still in the regime of linear response. However, the study of nonlinear phenomena also ("shear thinning," a decrease of the effective viscosity with increasing shear rate, or "shear melting" of colloidal crystals, etc.) may be of interest. In addition, one can study nonsteady state transient behavior, as it occurs, for example, after a sudden change from one thermodynamic state to another, and one wishes to study the approach of the system to its new thermal equilibrium. Classical examples of this problem are nucleation of fluid droplets in a supersaturated gas, or the kinetics of phase separation in a binary mixture ("spinodal decomposition") after a temperature quench. However, such processes are often too slow, and cannot be studied by NEMD, and one has to resort to a simulation of a coarse-grained model by nonequilibrium Monte Carlo (NEMC). This approach is suitable to deal also with irreversible growth processes far from equilibrium, such as diffusion-limited aggregation (DLA). This is an example of a mechanism of structure formation on mesoscopic scales of length and time that was discovered by simulations, and still lacks a good understanding in terms of the analytical theory.

In the following, the salient features of a few important simulation methods (classical MD, MC, PIMC) are briefly described. Also, limitations of simulations (e.g., due to the small size of the simulated system) are mentioned, and the extent to which these limitations can be overcome are discussed.

MD Algorithms

Consider a system of N particles (atoms) with Cartesian coordinates, $\mathbf{X} = \{\mathbf{r}_i\}$, $i = 1, \dots, N$, in a d -dimensional space. The dynamics then is described by Newton's equations of motion, $m_i \ddot{\mathbf{r}}_i = \mathbf{f}_i = -\partial U_{\text{pot}}/\partial \mathbf{r}_i$, m_i being the mass of the i th particle, $\mathbf{f}_i$ the force acting on it. This force is assumed to be entirely due to interactions with other particles: $U_{\text{pot}}(\mathbf{X}) = U_{\text{pot}}(\mathbf{r}_1, \dots, \mathbf{r}_N) = \sum u(|\mathbf{r}_i - \mathbf{r}_j|)$, where the sum extends once over each pair i, j of particles, and it has been assumed for simplicity that U_{pot} is pairwise additive. Then $\mathbf{f}_i = -\sum_j \partial u(|\mathbf{r}_i - \mathbf{r}_j|)/\partial \mathbf{r}_i$. Note that $E = E_{\text{kin}} + U_{\text{pot}} = \sum_i m_i \dot{\mathbf{r}}_i^2/2 + U_{\text{pot}}$ is a constant of motion ($\dot{E} = dE/dt = 0$).

MD now means that Newton's equations of motion are integrated numerically, by a computationally efficient scheme, such as Verlet's algorithm

$$\mathbf{r}_i(t+\delta t) = 2\mathbf{r}_i(t) - \mathbf{r}_i(t-\delta t) + \frac{1}{m_i} (\delta t)^2 \mathbf{f}_i(t) + O\{(\delta t)^4\} \quad [1]$$

where δt is the MD time step, and the velocity $\mathbf{v}_i(t)$ is updated similarly,

$$\mathbf{v}_i(t) = [\mathbf{r}_i(t+\delta t) - \mathbf{r}_i(t-\delta t)]/[2(\delta t)] + O\{(\delta t)^3\} \quad [2]$$

This algorithm is manifestly time-reversible and in spite of inevitable errors due to the discreteness of the time step δt , it keeps an important symmetry property of Newton's equations. To understand how large δt can be chosen, consider argon as an example, where atoms interact with a Lennard-Jones potential, $u_{\text{LJ}} = 4\varepsilon[(\sigma/r)^{12} - (\sigma/r)^6]$, with $\sigma \approx 3.4 \text{ \AA}$, $\varepsilon/k_B \approx 120 \text{ K}$ (k_B = Boltzmann's constant), and $m \approx 6.6 \times 10^{-23} \text{ g}$. Rescaling coordinates ($\mathbf{r}^* \equiv \mathbf{r}/\sigma$) yields ($\mathbf{r}_{ij}^* \equiv \mathbf{r}_i^* - \mathbf{r}_j^*$)

$$\mathbf{r}^*(t+\delta t) = 2\mathbf{r}^*(t) - \mathbf{r}^*(t-\delta t) - (\delta t/\tau_0)^2 \frac{\mathbf{r}_{ij}^*}{|\mathbf{r}_{ij}^*|} \times \sum_{j(\neq i)} [(\mathbf{r}_{ij}^*)^{-13} - (\mathbf{r}_{ij}^*)^{-7}/2] \quad [3]$$

where the natural time unit τ_0 of MD was defined as $\tau_0 = (m\sigma^2/48\varepsilon)^{1/2}$ which is roughly $\tau_0 \approx 3.1 \times 10^{-13} \text{ s}$ for argon. In order to keep numerical errors small, one needs to choose $\delta t = 0.03 \tau_0$ (or smaller), that is, $\delta t \approx 10^{-14} \text{ s}$. So even with a million time steps, one only reaches a real time of $\sim 10 \text{ ns}$.

As mentioned above, from a statistical mechanics point of view this algorithm realizes the microcanonical NVE ensemble. Temperature T is then inferred from the kinetic energy,

$$\begin{aligned}
T &= \langle \hat{T} \rangle_{\text{NVE}}, \\
\hat{T} &= 2E_{\text{kin}} / (3k_B N) \\
&= \sum_{i=1}^N m_i v_i^2 / (3k_B N)
\end{aligned} \tag{4}$$

Note that N is finite (typically $10^2 \leq N \leq 10^6$) and hence temperature fluctuations are non-negligible. These fluctuations contain information on the specific heat C_V , since $[\langle \hat{T}^2 \rangle - \langle \hat{T} \rangle^2] / \langle \hat{T} \rangle^2 = 2(1 - 3k_B/2C_V) / (3N)$. Since the “length” of an MD run (i.e., its number of time steps) is finite, these fluctuations of T cause a statistical error in the estimation of temperature.

The pressure p can be estimated using the virial theorem,

$$p = \langle \hat{P} \rangle_{\text{NVE}}, \quad \hat{P} = \left(2E_{\text{kin}} + \sum_i \mathbf{r}_i \cdot \mathbf{f}_i \right) / 3V \tag{5}$$

and again statistical fluctuations need to be considered.

It is often desirable to realize the canonical (NVT) rather than the microcanonical (NVE) ensemble. In an MD framework, this can be done by extending the Lagrangian of the system by a variable, representing the thermostat which has a fictitious “mass” Q . This yields the Nose–Hoover algorithm, where Newton’s equations of motion are extended by a “friction”-like term,

$$\ddot{\mathbf{r}}_i = \mathbf{f}_i / m_i - \zeta(t) \dot{\mathbf{r}}_i, \quad \dot{\zeta} = \left[\sum_i m_i v_i^2 - 3Nk_B T \right] / Q \tag{6}$$

Thus the “friction coefficient” $\zeta(t)$ fluctuates around zero, responding to the imbalance between the instantaneous kinetic energy and the intended canonical average. The total energy no longer is conserved, and energy fluctuations are linked to the specific heat as ($\hat{H}$ is the Hamiltonian)

$$NC_V / k_B = \left[\langle \hat{H}^2 \rangle_{\text{NVT}} - \langle \hat{H} \rangle_{\text{NVT}}^2 \right] / (k_B T)^2 \tag{7}$$

It is important to note, however, that dynamical correlation functions between observables such as $\langle A(0)A(t) \rangle$, where A is the observable of interest, are not precisely identical to the microcanonical ones. This is even more true for MD runs that realize the isothermal–isobaric (NpT) ensemble, where the pressure is given and the volume V rather fluctuates, by coupling to the so-called “Andersen barostat.” Therefore, one often uses MD in NVT or NpT ensembles for equilibration (and the computations of static averages) only, generating a set of well-equilibrated system configurations, which are then used as initial states for runs where thermostats and/or barostats are switched off, realizing the runs in the NVE ensemble, where $\langle A(0)A(t) \rangle$ is computed as a time average, $\int_0^{t_{\text{obs}}} dt_0 [A(t_0)A(t_0+t)] / (t_{\text{obs}} - t)$, t_{obs} being the total “observation time” over which the run is extended.

In order to judge whether t_{obs} is large enough, it is important to know what the slow observables in the system are. A typical reason for slow relaxation is the presence of large “objects” of correlated sets of particles in the systems, which show slow motions. An example is “critical slowing down” near second-order phase transitions, where large “clusters” of the variable representing the local order parameter occur. For example, near the liquid–gas critical point, large density fluctuations occur which are correlated over a correlation length ξ which diverges at criticality in the thermodynamic limit ($N \rightarrow \infty$), and then also the corresponding relaxation time τ diverges. Another example are polymer chains in solution or melt – a flexible polymer consisting of N monomers relaxes in the melt on a timescale $\tau \approx N^2$ in the Rouse limit (unentangled chains) or even $\tau \propto N^3$ in the reptation limit of entangled chains (i.e., a snakelike motion of the chains along their own contour). Thus, MD simulations of critical phenomena as well as of polymeric systems or other soft matter systems with objects containing many subunits (membranes, microemulsions, etc.) are intrinsically difficult.

However, it should also be noted that another reason for slow relaxation are conservation laws. In the NVE and NVT ensembles, the average density $\langle \rho \rangle = N/V$ is strictly conserved. Assuming for local fluctuations in density $\delta \rho(\mathbf{r}, t) - \langle \rho \rangle$ that Fick’s law holds, a gradient $\nabla(\delta \rho(\mathbf{r}, t))$ causes a density current $\mathbf{j}(\mathbf{r}, t)$, D being a diffusion coefficient, $\mathbf{j}(\mathbf{r}, t) = -D \nabla(\delta \rho(\mathbf{r}, t))$. The conservation law implies the continuity equation $\partial \rho(\mathbf{r}, t) / \partial t + \nabla \cdot \mathbf{j}(\mathbf{r}, t) = 0$, and hence a diffusion equation for $\delta \rho(\mathbf{r}, t)$ results, $\partial(\delta \rho(\mathbf{r}, t)) / \partial t = D \nabla^2(\delta \rho(\mathbf{r}, t))$. The Fourier components $\delta \rho_{\mathbf{k}}(t)$ of $\delta \rho(\mathbf{r}, t)$ then satisfy the equation

$$\begin{aligned}
\frac{d}{dt} \delta \rho_{\mathbf{k}}(t) &= -Dk^2 \delta \rho_{\mathbf{k}}, \\
\delta \rho_{\mathbf{k}}(t) &= \delta \rho_{\mathbf{k}}(0) \exp(-Dk^2 t)
\end{aligned} \tag{8}$$

Therefore, the dynamic correlation function of density fluctuations at long wavelengths decays very slowly,

$$S_{\rho}(\mathbf{k}, t) \equiv \langle \delta \rho(-\mathbf{k}, 0) \delta \rho(\mathbf{k}, 0) \rangle = S(k) \exp(-t/\tau_k), \quad \tau_k = (Dk^2)^{-1} \tag{9}$$

Equation [9] demonstrates the “hydrodynamic slowing down” $\tau_k \rightarrow \infty$ for $k \rightarrow 0$. Of course, due to finite size effects, this divergence of the relaxation time is cut off; in a (hyper)cubic system of linear dimension L with periodic boundary conditions, the smallest

wave number is $k_{\min} = (2\pi)/L$, and hence the largest relaxation time is $\tau_{\max} = L^2/(4\pi^2 D)$. Clearly, this phenomenon makes the equilibration of very large systems difficult.

A brief mention is made of the way transport coefficients are estimated from simulations. The simplest case are self-diffusion coefficients, where one can apply the Einstein relation, following the mean square displacements of “tagged” particles, $\langle [r(t) - r(0)]^2 \rangle = 2dDt$, $t \rightarrow \infty$. Transport coefficients relating to collective properties can be extracted from Green-Kubo relations, for example, the shear viscosity is related to time correlations of the off-diagonal components of the pressure tensor σ_{xy} ,

$$\eta = \int_0^\infty dt \langle \sigma_{xy}(0) \sigma_{xy}(t) \rangle / (Vk_B T) \quad [10]$$

where

$$\sigma_{xy} = \sum_{i=1}^N \left\{ m_i v_i^x v_i^y + \frac{1}{2} \sum_{j(\neq i)} x_{ij} f_i^y(r_{ij}) \right\} \quad [11]$$

Similar relations can be written down for thermal conductivity, electrical conductivity, interdiffusion coefficient in mixtures, etc. Alternatively, transport coefficients can be estimated from NEMD, creating via suitable boundary conditions, a steady state of the appropriate quantity (mass density of a particle species, heat, momentum density) through the system.

Importance Sampling Monte Carlo Methods

Most MC calculations aim at the estimation of thermodynamic averages by importance sampling methods. Considering a variable $A(X)$ where X denotes a point in phase space, such averages are defined in classical statistical mechanics by

$$\langle A \rangle = \int dX P_{\text{eq}}(X) A(X), \quad P_{\text{eq}}(X) = (1/Z) \exp[-\hat{H}(X)/k_B T] \quad [12]$$

where $\hat{H}(X)$ is the Hamiltonian of the system, and Z is the partition function

$$Z = \int dX \exp[-\hat{H}(X)/k_B T] \quad [13]$$

Note that when one deals with the simulation of a fluid, momenta of the particles need not be included in X since they cancel out from all averages. In addition, X may denote any subset of variables only, for the problem of interest. For example, dealing with the phase transition of an anisotropic magnet, one may approximate the crystal lattice as rigid, and then each lattice site i carries as single degree of freedom an Ising spin, $S_i = \pm 1$. The Ising model Hamiltonian then is

$$\hat{H}_{\text{Ising}} = -J \sum_{(i \neq j)} S_i S_j - h \sum_i S_i \quad [14]$$

assuming a nearest neighbor pairwise exchange energy J and a coupling to a magnetic field h (choosing units such that the magnetic moment per spin is unity). Here X stands for $S_1, S_2, \dots, S_N$, that is, the phase space is discrete, and $\int dX$ stands symbolically for summation over all 2^N microstates of the system.

Now the basic idea of MC sampling is to consider the task of computing $\langle A \rangle$ as a problem of numerical integration over the phase space, where one would approximate $\langle A \rangle$ by an average $\bar{A}$ over M points only,

$$\bar{A} = \frac{1}{M} \sum_{v=1}^M P_{\text{eq}}(X_v) A(X_v) \quad [15]$$

The difficulty, of course, is that the integration space is very high dimensional, and it is a problem to choose the sample of M points X_v appropriately. It is easy to see that a regular grid of points X_v does not work, but a uniform random sampling of phase space (“simple sampling”) does not work either in most cases. A notable exception, of course, is the sampling of nonthermal random distributions, for example, the random occupation of lattice sites in a mixed crystal $A_x B_{1-x}$ by A and B atoms can be simulated straightforwardly. Choosing random numbers η uniformly distributed between zero and unity, an A -atom is assigned to the considered lattice site if $\eta < x$, while otherwise the site is taken to be occupied by a B -atom. This straightforward use of MC sampling works only if the occupation probabilities of neighboring lattice sites are independent of each other, however. Other physically relevant problems where simple sampling works are the generation of random walks and (short) self-avoiding walks, the bond percolation problem (nearest neighbor links connecting lattice sites are chosen at random conducting or isolating, to understand the electrical conductivity of disordered solids), etc. However, simple sampling is not useful for the estimation of thermal averages when N is large. The reason is that it is only a very small region of phase space where the important contributions come from, and via simple sampling only very few points X_v would be drawn from this important region. This is seen when one considers the reduced distribution function $P_N(m)$ of the density m of some extensive variable, for example, the magnetization of the Ising

magnet, $m = (1/N) \sum S_i$, where the sum runs over all lattice sites, or the internal energy, etc., $P_N(m) = \int dX \delta(m - (1/N) \sum S_i) P_{eq}(X)$. Such distributions exhibit sharp peaks at the (*a priori* unknown) average value $\langle m \rangle$, of width proportional to $1/\sqrt{N}$. It is clear, however, that from simple sampling for large N , almost no states would be generated in the region where $P_N(m)$ has its peak; most of the computational effort would be wasted for exploring a completely uninteresting part of the phase space.

Thus a method is needed that leads one automatically to the important region of the phase space. Such a method is provided by the Metropolis importance sampling algorithm, which yields states X_v with a probability proportional to the Boltzmann factor. This is achieved by generating a Markov chain of states recursively one from the other, $X_v \rightarrow X_{v+1} \rightarrow X_{v+2} \rightarrow \dots$, using a properly chosen transition probability. For a fluid, the move from X to X' may mean a random displacement of a single randomly chosen particle; for an Ising model, it may mean a single spin is chosen at random and considered for a spin flip, or for exchange with one of its neighbors; but also flips of large clusters of spins in one move together may be carried out. Also moves that have no counterpart in reality are conceivable (e.g., in a dense polymer melt, one may select a pair of long chains that are close by each other, cut them in the middle, and reconnect the parts differently than previously). Even though such moves need not represent any physically plausible dynamics, they may provide an efficient sampling of the phase space. The great flexibility in the choice of such moves, adapted to the problem one wishes to study, is one of the particular strengths of the MC methods.

The states X_v are distributed according to the Boltzmann factor $P_{eq}(X)$ if the transition probability $W(X \rightarrow X')$ satisfies the condition of detailed balance

$$P_{eq}(X)W(X \rightarrow X') = P_{eq}(X')W(X' \rightarrow X) \quad [16]$$

For instance, a choice that satisfies eqn [16] is simply

$$W(X \rightarrow X') = \begin{cases} \tau_0^{-1}, & \text{if } \delta\hat{H} \equiv \hat{H}(X') - \hat{H}(X) < 0 \\ \tau_0^{-1} \exp(-\delta\hat{H}/k_B T), & \text{if } \delta\hat{H} \geq 0 \end{cases}$$

Here, a constant τ_0 has been arbitrarily introduced to set a timescale, so that W gets the meaning of a transition probability per unit time (but one may choose $\tau_0 = 1$, of course, and normally one considers one Monte Carlo step (MCS) per degree of freedom as the natural unit of the MC “time”). This notion is useful, since MC sampling can be interpreted as “time averaging” along stochastic trajectories in phase space, described by a master equation for the probability $P(X, t)$ that a state X occurs at time t ,

$$\frac{d}{dt}P(X, t) = -\sum_{X'} W(X \rightarrow X')P(X, t) + \sum_{X'} W(X' \rightarrow X)P(X', t) \quad [17]$$

This rate equation describes the balance between the loss of probability by all processes $X \rightarrow X'$ that lead away from the considered state and the gain of probability due to the inverse process. Obviously, $dP/dt = 0$ if $P = P_{eq}(X)$, due to the detailed balance principle, eqn [16].

Of course, the dynamical properties of a system described by such a stochastic trajectory through phase space generated via MC will differ in general from dynamic properties deduced from the deterministic MD trajectories. In fact, the MC dynamics is of physical significance only when one deals with systems for which the considered degrees of freedom are a (slow!) subset weakly coupled to the remaining (fast!) degrees of freedom, that behave like a heat bath. This is the case for the Ising magnet and for diffusion in solid alloys $A_x B_{1-x}$, for instance. In both cases the phonons of the crystal act like a heat bath, causing random spin flips or random jumps of A or B atoms to vacant sites, respectively. Often the MC dynamics is considered as fairly realistic for random growth or aggregation phenomena on mesoscopic scales, such as diffusion-limited aggregation (DLA).

The dynamic interpretation of MC sampling in terms of a stochastic trajectory in phase space is important for the understanding of “statistical error,” since the subsequently generated states $\{X_v\}$ are highly correlated with each other. In fact, one can show that the expected mean square statistical error becomes

$$\langle (\delta A)^2 \rangle = \frac{1}{n} [\langle A^2 \rangle - \langle A \rangle^2] (1 + 2\tau_{AA}/\delta t) \quad [18]$$

where

$$\tau_{AA} = \int_0^\infty \Phi_{AA}(t) dt, \quad \Phi_{AA}(t) \equiv [\langle A(0)A(t) \rangle - \langle A \rangle^2] / [\langle A^2 \rangle - \langle A \rangle^2] \quad [19]$$

if n observations $\{A_{\mu_j}\}$ of the observable A separated by time increment δt are taken. If these n observations were statistically independent, the enhancement by the “dynamic factor” $(1 + 2\tau_{AA}/\delta t)$ would be absent. As noted in the discussion of MD methods, relaxation times τ_{AA} get large near critical points, or when one considers long wavelength Fourier components of a conserved quantity (“critical slowing down,” “hydrodynamic slowing down,” also hamper MC!). Also the questions of whether or not an algorithm is ergodic, and how fast equilibrium is reached or whether hysteresis may occur, etc., are important for both MD and MC.

A further limitation of simulations that may need consideration are finite size effects. Considering Fourier components such as $\delta\rho_k$ (eqns [8] and [9]), one must note that in a finite system with periodic boundary conditions k -space is quantized. For example, if one has a cubic simulation cell $L \times L \times L$, the allowed wave vectors are $\mathbf{k}_n = (2\pi/L)(n_x, n_y, n_z)$ where n_x are integers. With respect to

static phenomena, the gap in the spectrum of long wavelength modes affects physical properties for which these modes are important (e.g., long wavelength phonons cause the T^3 law for specific heats, if the crystal is treated by quantum statistical mechanics; long wavelength magnons in a Heisenberg ferromagnet cause a divergence of the longitudinal and transverse susceptibilities; capillary waves cause a divergence of interfacial widths, etc.). Thus for many physical properties, it is advisable to repeat the simulation for a range of values of L , and carry out a suitable extrapolation of the results to the thermodynamic limit, $L \rightarrow \infty$.

The problem of finite size effects is particularly cumbersome when one deals with phase transitions. However, the study of phase transitions is a problem for which simulations are often necessary, and, in fact, useful! One approach to overcome the limitation of finite size for such problems relies on the concept of finite size scaling. Consider, as a simple example, the transition of the Ising model {eqn [14]} from the paramagnetic phase at $T > T_c$ to a ferromagnetic state at $T < T_c$. Near the critical temperature T_c , spontaneous magnetization m_{sp} and susceptibility χ are singular in the thermodynamic limit, $m_{sp} \propto (1-T/T_c)^\beta$, $\chi \propto |1-T/T_c|^{-\gamma}$, where β, γ are “critical exponents.” Varying H for $T < T_c$, however, m at $H = 0$ has a jump singularity from $-m_{sp}$ to $+m_{sp}$, χ then has a delta-function singularity: this is a special case of a first-order transition.

In a finite system, however, these singularities are always rounded. For example, χ for $H = 0$ as a function of T does not diverge, there is a peak of finite height only, which also is shifted away from T_c . Thus, it is a nontrivial problem to estimate both T_c and other critical properties (such as exponents) with sufficient accuracy.

For critical phenomena, finite size scaling rests on a comparison of lengths: the linear dimension L scales with the correlation length $\xi \propto |1-T/T_c|^{-\nu}$ of the system. As a consequence, near T_c moments of the order parameter distribution depend on L and ξ basically via a scaling function of the ratio L/ξ , apart from a power-law prefactor $\langle |m|^k \rangle = L^{-k\beta/\nu} \tilde{M}_k(L/\xi)$, $L \rightarrow \infty, k$ integer, $\tilde{M}_k$ being a “scaling function”! Particularly useful are, thus, suitable ratios of moments where the power law prefactors cancel out, such as the reduced fourth-order cumulant

$$\begin{aligned} U_L(T) &= 1 - \langle m^4 \rangle / [3 \langle m^2 \rangle^2] \\ &= \tilde{U}(L/\xi), \quad L \rightarrow \infty \end{aligned} \quad [20]$$

Since $\xi \rightarrow \infty$ as $T \rightarrow T_c$, all curves $U_L(T)$ must intersect at $T = T_c$ in a universal value $\tilde{U}(0)$; note that $U_L(T) \rightarrow 2/3$ for $T < T_c$ as $L \rightarrow \infty$, while $U_L(T) \rightarrow 0$ for $T > T_c$. If such a unique intersection point is found, it thus serves to find the location of T_c . If the intersections of different pairs $U_L(T)$, $U_{L'}(T)$ scatter, on the other hand, one can conclude that corrections to scaling are still pronounced, and the study of larger systems is required. At T_c , one also finds that $\langle |m| \rangle \propto L^{-\beta/\nu}$, $\chi \propto L^{\gamma/\nu}$, and thus one can estimate critical exponents.

Also, first-order transitions are rounded; while in the Ising model for $T < T_c$, two phases with $\pm m_{sp}$ occur precisely at $H = 0$, the distribution function of the magnetization simply is $P_\infty(m) = [\delta(m - m_{sp}) + \delta(m + m_{sp})]/2$, and for finite L , one observes two broadened peaks not only at $H = 0$ but over a range ΔH of fields, with $\Delta H \propto L^{-d}$, inversely proportional to the volume of the system. But the location of the first-order transition is found accurately from the “equal weight rule” for the two peaks.

The sampling of $P_L(m)$ is very useful since one can show that for $T < T_c$, one has $P_L(0)/P_L(m_{sp}) \propto \exp(-2L^{d-1}\sigma/k_B T)$, σ being the interfacial tension between the coexisting phases. Use of this formula, in fact, is one of the most powerful recipes to estimate interfacial free energies from simulations. Of course, $P_L(0)/P_L(m_{sp})$ for large L is extremely small, and thus this ratio cannot be sampled directly, but needs more advanced schemes that are not described here due to lack of space, such as “umbrella sampling” or “multicanonical MC.”

Of course, the above comments discuss the study of phase transitions by simulations only in a nutshell, and the reader is directed to the “Further reading” section for further details.

Path-Integral Monte Carlo (PIMC)

Thermal averages for a quantum system are calculated, and thus eqns [12] and [13] are rewritten appropriately

$$\begin{aligned} \langle \hat{A} \rangle &= Z^{-1} \text{Tr} \exp(-\hat{H}/k_B T) \hat{A}, \\ Z &= \text{Tr} \exp(-\hat{H}/k_B T) \end{aligned} \quad [21]$$

using a notation that emphasizes the operator character of the Hamiltonian $\hat{H}$ and observable $\hat{A}$. For simplicity, consider first the case of one particle in a potential $V(x)$ in one dimension, where $\hat{H} = -(\hbar^2/2m)d^2/dx^2 + V(x)$, m being the mass of the particle. In position representation $Z = \int dx \langle x | \exp(-\hat{H}/k_B T) | x \rangle$, $|x\rangle$ being an eigenvector of the position operator. The problem now is that $\hat{H} = \hat{E}_{kin} + \hat{V}(x)$, where $\hat{E}_{kin}$ and $\hat{V}(x)$ do not commute. Applying the Suzuki–Trotter formula, P being a positive integer

$$\begin{aligned} &\exp[-(\hat{E}_{kin} + \hat{V})/k_B T] \\ &= \lim_{P \rightarrow \infty} [\exp(-\hat{E}_{kin}/k_B TP) \exp(-\hat{V}/k_B TP)]^P \end{aligned} \quad [22]$$

one can reduce Z to $\langle x_{P+1} = x_1 \rangle$

$$Z = \lim_{P \rightarrow \infty} \left(\frac{k_B T m P}{2\pi\hbar^2} \right)^{P/2} \int dx_1 \dots \int dx_P \times \exp \left(\left[-\frac{\kappa}{2} \sum_{s=1}^P (x_s - x_{s+1})^2 - P^{-1} \sum_{s=1}^P V(x_s) \right] / k_B T P \right) \quad [23]$$

where $\kappa \equiv (k_B T / \hbar)^2 m P$. Apart from the prefactor, eqn [23] is the configurational partition function of a ring polymer within the framework of classical statistical mechanics: P beads are coupled by harmonic springs with spring constant κ , and are exposed to a potential $V(x)/P$.

This approach is straightforwardly generalized to a system of N interacting quantum particles, if the quantum mechanical exchange is neglected: one ends up with a system of N classical cyclic “polymer chains.” As a result of this isomorphism, methods for simulating classical systems (MC, MD) can be carried over to such quantum-mechanical problems, too. At high temperatures, κ gets very large, the cyclic chain contracts essentially to a point, while at low T the chains are spread out, representing zero-point motions. The lower the T is, the larger the P has to be: if σ is a characteristic distance over which the potential $V(x)$ changes, one must have $\hbar^2 / m \sigma^2 \ll k_B T P$ so that two neighbors along the “polymer chain” are at a distance much smaller than σ . The typical size of the ring polymer, of course, is of the order of the thermal de Broglie wavelength λ_T : at very low temperatures (or for very light particles such as He atoms) λ_T becomes comparable to the interparticle spacing, and the precise formulation of the problem requires the correct incorporation of the statistics of the particles (Bose–Einstein versus Fermi–Dirac) into the formalism. For fermions, this leads to the famous difficulty known as “minus sign problem” – the distribution to be sampled loses its interpretation as a probability distribution, because it is no longer non-negative everywhere. Thus the study of systems such as liquid ^3He (or fermions on a lattice, a problem to which a similar formulation based on the Suzuki–Trotter decomposition is applicable) is still an active area of research. However, one may stress that the simplified formulation of PIMC (or PIMD, respectively) that ignores the statistics of the particles is useful (and indispensable!) to study the thermal properties of crystals (such as solid Ne or Ar, SiO_2 , polyethylene etc.) at low temperatures (and obtain temperature dependences of lattice parameters, elastic constants etc., that are compatible with the third law of thermodynamics).

Conclusion

In this article, the basic foundations of three important simulation methods (classical MD and MC, PIMC) have been briefly described, and some technical limitations as well as recipes of how they can be overcome have also been mentioned. However, there are many “tricks of the trade” that could not be described, due to lack of space: for example, one can switch on or off arbitrary perturbations or parts of the interparticle forces, and combine this with suitable thermodynamic integration methods to gain information on thermodynamic excess potentials, etc. Very important variations are also possible by a suitable choice of various boundary conditions (e.g., a combination of “tilted periodic” with “antiperiodic” boundary conditions allows the study of tilted interfaces in Ising systems). An important aspect also is that an analysis of conceptually important quantities (e.g., Voronoi polyhedra distributions in amorphous solids, ring statistics in molten silica, orientational order parameters in two-dimensional melting, etc.) is readily possible with simulations, while one can infer these quantities from experiment at best indirectly. Many such extensions of the techniques described here, as well as further simulation methods, and last but not the least, numerous application examples can be found in the “Further reading” section.

Nomenclature

a_i, α_i ($i = 1-3$)	real-space lattice parameters ($\text{\AA}, ^\circ$)
b_i, β_i ($i = 1-3$)	reciprocal-space lattice parameters ($\text{\AA}, ^\circ$)
B	matrix which produces a Cartesian coordinate system for reciprocal space ($\text{\AA}^{-1}$)
d	lattice-plane spacing ($\text{\AA}$)
h	reciprocal lattice vector (reciprocal lattice units)
h_c	reciprocal lattice vector in Cartesian coordinates ($\text{\AA}^{-1}$)
h_1	reciprocal lattice vector in lab frame ($\text{\AA}^{-1}$)
h_φ	reciprocal lattice vector in frame of φ axis ($\text{\AA}^{-1}$)
K	diffracted wave vector ($\text{\AA}^{-1}$)
K_0	incident wave vector ($\text{\AA}^{-1}$)
N	reference vector ($\text{\AA}^{-1}$)
Q	scattering vector ($\text{\AA}^{-1}$)
$R(\zeta)$	rotation matrix describing the effect of diffractometer axis ζ (unitless)
U	orientation matrix (unitless)
α_0	kappa diffractometer angle ($^\circ$)
$\gamma, \delta, \eta, \alpha$	Z-axis diffractometer angles ($^\circ$)
δ, ν, η, μ	S2D2 diffractometer angles ($^\circ$)
2θ	total scattering angle ($^\circ$)
$2\theta, \theta, \chi, \varphi$	four-circle Eulerian diffractometer angles ($^\circ$)
$2\theta, \theta_\kappa, \kappa, \varphi_\kappa$	kappa diffractometer angles ($^\circ$)
λ	wavelength ($\text{\AA}$)
ψ	azimuthal angle ($^\circ$)

Introduction

When a monochromatic, collimated beam of radiation (X-rays or neutrons) is incident upon a stationary single crystal, the diffraction condition will probably be satisfied for few if any reflections, depending on a number of parameters such as the size of the unit cell, crystal mosaicity, and the energy spread of the radiation. It is even less likely that any particular reflection will be observed, and useful information, such as a reflection's integrated intensity, is not immediately available. Over the years, several methods of collecting scattering data have developed. The earliest X-ray experiments were performed with polychromatic radiation and a two-dimensional (2D) detector (photographic film); known as the Laue method, this technique has remained useful for quick sample alignment and has found new use in timing experiments in which an entire diffraction pattern is collected in a very short exposure. The powder-diffraction method consists of literally grinding the sample to a powder, effecting an ensemble average over all sample orientations; a powder-diffraction pattern is then collected with 1D scan of the detector. The rotation method consists of

rotating a single-crystal sample through a given angle while measuring the pattern on a 2D detector with the use of modern image plates or charge-coupled device (CCD) detectors; this is the standard technique for macromolecular protein crystallography. While the above methods are practical for collecting integrated intensities of sharp, well-defined Bragg points, they may compromise on measurement of diffuse features. As an alternative, multicircle diffractometry uses computerized control of a high-precision goniometer (i.e., angle-positioning instrument) in order to hold both sample and detector at precise orientations, becoming a powerful tool to provide quantitative scattering data at well-defined positions in reciprocal space. Monochromatic radiation is used and, typically, observed by a point detector (a detector with a small, well-defined aperture).

Multicircle diffractometry is regularly applied to studies of systems in which orientational information cannot be sacrificed, such as measurement of pole figures for texture analysis or residual stress analysis; grazing-incidence or grazing-exit diffraction for studies of surfaces, thin films, and superlattices; and observation of diffuse scattering due to short-range order, defects such as twins or voids, or thermal diffuse scattering. Two examples of scattering data that require multicircle collection methods are shown in Figure 1. The reciprocal-space map in Figure 1a is from an Ni film grown on MgO(0 0 1); the peaks in the diffraction pattern are used to identify the various epitaxial orientations of the Ni crystal relative to the substrate, as well as the film's strain and mosaic spread. Figure 1b shows integrated intensities from two truncation rods of an epitaxial SrTiO₃ film on Si(0 0 1); the rods are continuous, diffuse features which can be analyzed to determine the atomic structure of the film and interface. The foremost drawback of multicircle diffractometer methods, compared to the other methods mentioned above, is that data are collected relatively slowly, often one point at a time rather than over a wide range of reciprocal space at once. The fairly involved calculations of the technique, described in some detail below, are no longer the issue that they once were, given the power and economy of modern computers; various diffractometer-control software packages are available.

In this article, several geometries of multicircle diffractometers, beginning with the standard four-circle Eulerian diffractometer, are reviewed. An overview of the transformation between reciprocal space and angle space is given, and various options in operating a diffractometer are described. Other diffractometer geometries will then be presented, including alternate four-circle geometries, then progressing to five- and six-circle geometries. Throughout the article, an attempt is made to point out potential sources of confusion, such as those caused by conflicting systems of nomenclature; correspondingly, the names of angles used here may differ from those in the literature or those implemented on various instruments. In that vein, it is to be noted that this article uses the term "multicircle diffractometers" to refer to instruments whose circles rotate the sample or detector; additional circles, which are used for polarization analysis or wavelength-dispersive analysis of the radiation, are not counted.

Four-Circle Eulerian Geometry

The basic four-circle diffractometer geometry is shown in Figure 2. The sample sits at the center of rotation on the φ circle, which rotates on the χ circle. The χ and φ circles together constitute a Eulerian cradle, for which this geometry is named. The Eulerian cradle then rotates on the θ circle. The detector rotates on the 2θ circle. The θ -axis is collinear with the 2θ axis; since both axes are perpendicular to the incident beam, this diffractometer is classified as normal-beam geometry. The scattering plane is defined as the plane that contains the diffracted wave vector K and the incident wave vector K_0 , as well as their difference, the scattering vector Q , as shown in Figure 2b. The scattering plane is often horizontal for a laboratory-based X-ray diffractometer, so that the effects of gravity are minimized; at synchrotron sources the scattering plane is usually vertical, to take advantage of the (typically) s-polarization of the radiation and the higher degree of collimation in the vertical plane.

The correct operation of a diffractometer hinges on its being properly configured. Figure 2a shows the Eulerian four-circle diffractometer with all angles at their zero positions, in which case the direct beam travels along the axis of the χ circle, defining the zero position of θ ; the detector intercepts the direct beam, defining the zero of 2θ ; and the θ and φ axes are collinear, defining the zero of χ . The zero of φ is arbitrary. The sense of rotation, as shown in Figure 2b, is left-handed for all axes except χ .

The origin of the rather inelegant naming system is historical. In Bragg's original derivation of X-ray diffraction, the incident and exit X-ray beams both made an angle of θ with the diffracting planes, for a total scattering angle of 2θ . For normal-incidence diffractometers, the scattering angle is set by a single rotation typically labeled 2θ . The sample angle θ is not necessarily equal to one-half of 2θ , except in the special case of some three-circle diffractometers where the axes are mechanically coupled with a 1:2 gear ratio. Thus, although Bragg's law is often written as $\lambda = 2d \sin \theta$, it is better written as

$$\lambda = 2d \sin(2\theta/2) \quad [1]$$

where λ is the wavelength and d is the lattice-plane spacing. The angle between θ and 2θ is ω , which is defined as

$$\omega = \theta - (2\theta)/2 \quad [2]$$

The case of $\omega = 0$ is called the symmetric mode of diffraction. Unfortunately, there is no standard notation even for the most common type of diffractometer, and the θ circle is sometimes labeled ω .

Common angle scans performed on a four-circle Eulerian diffractometer include θ and $\theta/2\theta$ scans. A scan of the θ -axis probes the sample at a given magnitude of the scattering vector $|Q|$ (defined below in eqn [9]). As an example, a θ scan might be used to probe a sample's mosaic spread; one possible source of instrumental broadening for this scan would be the beam divergence. In the $\theta/2\theta$ scan, the 2θ circle rotates at twice the rate of the θ circle. The trajectory of the $\theta/2\theta$ scan is radially outward from the origin of reciprocal space (i.e., Q increases in magnitude, with constant direction). This two-angle scan might be used to measure variations in a sample's lattice-parameter or strain; a source of instrumental broadening could be the radiation's band pass (i.e., the spread in

Figure 1 Two examples of thin-film diffraction data collected on a six-circle diffractometer. In both cases, the reciprocal lattice of the substrate material is used as a reference. (a) Reciprocal-space map of a 12 nm film of Ni grown at MgO(001). The map was made at $L = 0.05$ reciprocal lattice units, with the incident beam set at a grazing angle of 0.2° ; the contours are spaced logarithmically. The sharp peak near the main MgO(002) peak at $H = 2, K = 0$ shows that the substrate is somewhat twinned. The peak marked A corresponds to an Ni(200) peak with relaxed cube-on-cube epitaxy. The peaks marked B, C, and C' are Ni(111) peaks due to regions with the epitaxial relationship $(110)\text{Ni} \parallel (001)\text{MgO}$. (b) Truncation-rod data of five unit cells of SrTiO_3 grown on $\text{Si}(001)$, collected with a fixed 0.3° angle of incidence. Circles indicate integrated intensities along the (20L) rod, and diamonds represent the (31L) rod (vertically offset for clarity). Data points very close to the bulk Bragg points (202), (311), and (313) were not measured, since they have very high intensities and no surface sensitivity.

Figure 2 Diagram of a four-circle Eulerian diffractometer with (a) all angles at 0° and (b) all angles with positive displacements. The coordinate system is shown in (a), while incident wave vector K_0 , diffracted wave vector K , scattering vector Q , and azimuthal angle ψ are shown in (b).

wavelength). A $\theta/2\theta$ scan is preferable to a single-axis 2θ scan because the reciprocal-space trajectory of a $\theta/2\theta$ scan is simpler to interpret. However, the power of modern multicircle diffractometry is to move to arbitrary positions and scan in arbitrary directions of the reciprocal space; the following sections of this article show how this is accomplished.

Angle Calculations

The Diffraction Equation

The fundamental problem in multicircle diffractometry is to map a sample's reciprocal-space coordinates to the diffractometer's angles: to measure the scattered intensity at a certain point in reciprocal space, what values should the angles have? The solution to this question was worked out by Busing and Levy for the case of a four-circle diffractometer, with extensions by many authors to other geometries. Here, the principles for the ideal four-circle case are outlined; detailed calculations for a variety of geometries can be found in the literature.

The question of mapping from reciprocal space to angle space could be restated as how to set the scattering vector Q equal to a desired reciprocal-lattice point h , that is,

$$h = Q \quad [3]$$

The two sides of eqn [3] must be written in the same reference frame and in the same coordinates; here one may choose to transform eqn [3] to $\text{\AA}^{-1}$ units in the laboratory frame. Beginning with the left-hand side of eqn [3], the transformation of reciprocal-lattice vector h from reciprocal-lattice coordinates (h , with no subscript) to lab coordinates (h_l) is achieved in a number of steps by successive application of a number of matrices. First, h in reciprocal-lattice units is transformed into Cartesian coordinates (h_c , in $\text{\AA}^{-1}$ units) via the matrix B :

$$h_c = Bh \quad [4]$$

where B is constructed from the lattice parameters. The matrix B is most easily expressed as a combination of real-space lattice parameters a_i , α_i and reciprocal-space lattice parameters b_i , β_i ($i = 1-3$):

$$B = \begin{pmatrix} b_1 & b_2 \cos \beta_3 & b_3 \cos \beta_2 \\ 0 & b_2 \sin \beta_3 & -b_3 \cos \beta_2 \cos \alpha_1 \\ 0 & 0 & 2\pi/a_3 \end{pmatrix} \quad [5]$$

where $a_i \cdot b_j = 2\pi\delta_{ij}$. Generally, B is not orthonormal, but the other matrices in this section are all orthonormal rotation matrices. The next step is to transform h_c into the coordinate system of the diffractometer's φ axis:

$$h_\phi = Uh_c \quad [6]$$

where U describes the orientation of the crystal relative to the diffractometer, and as such, is known as the orientation matrix. The determination of U is a critical step in multicircle diffractometry and is described in the next section. h_ϕ is then transformed into laboratory coordinates by the successive application of the diffractometer-axes rotation matrices R :

$$h_l = R(\theta)R(\chi)R(\phi)h_\phi \quad [7]$$

where

$$\begin{aligned}
R(\theta) &= \begin{pmatrix} \cos \theta & \sin \theta & 0 \\ -\sin \theta & \cos \theta & 0 \\ 0 & 0 & 1 \end{pmatrix} \\
R(\chi) &= \begin{pmatrix} \cos \chi & 0 & \sin \chi \\ 0 & 1 & 0 \\ -\sin \chi & 0 & \cos \chi \end{pmatrix} \\
R(\phi) &= \begin{pmatrix} \cos \phi & \sin \phi & 0 \\ -\sin \phi & \cos \phi & 0 \\ 0 & 0 & 1 \end{pmatrix}
\end{aligned} \tag{8}$$

Turning to the right side of eqn [3], the scattering vector or momentum transfer, Q , is defined as

$$Q = K - K_0 \tag{9}$$

where K and K_0 are the diffracted and incident wave vectors, respectively. Their magnitudes are equal and defined as

$$|K| = |K_0| = K = 2\pi/\lambda \tag{10}$$

The magnitude of Q is then

$$|Q| = \frac{2\pi}{d} = \frac{4\pi \sin(2\theta/2)}{\lambda} \tag{11}$$

It should be noted that numerous conventions exist for the definitions of eqns [9] and [10]. For example, the symbols s and s_0 or k' and k may be used for the diffracted and incident wave vectors respectively. These wave vectors are often defined without the factor of 2π in eqn [10]; correspondingly, the factors of 2π are removed from eqns [5] and [11]. Other common symbols for the scattering vector include G , H , and K .

In laboratory units, the incident wave vector is along the y -axis:

$$K_0 = \begin{pmatrix} 0 \\ K \\ 0 \end{pmatrix} \tag{12}$$

The diffracted wave vector is along the y -axis of the detector frame, which can be transformed into the lab frame with a rotation matrix for the 2θ axis:

$$\begin{aligned}
K &= R(2\theta) \begin{pmatrix} 0 \\ K \\ 0 \end{pmatrix}, \\
R(2\theta) &= \begin{pmatrix} \cos 2\theta & \sin 2\theta & 0 \\ -\sin 2\theta & \cos 2\theta & 0 \\ 0 & 0 & 1 \end{pmatrix}
\end{aligned} \tag{13}$$

The scattering vector Q , then, equals $[R(2\theta) - I] K_0$, where I is the identity matrix. Substitution into eqn [3] results in the basic diffractometer equation for a four-circle diffractometer:

$$R(\theta)R(\chi)R(\phi)UBh = [R(2\theta) - I] \begin{pmatrix} 0 \\ K \\ 0 \end{pmatrix} \tag{14}$$

Several possible generalizations of the above procedure are fairly straightforward to derive. For another diffractometer geometry, one simply incorporates the appropriate rotation matrices R into eqn [14]. One can also measure the directions of a diffractometer's rotation axes with, for example, an autocollimator, creating empirical R matrices rather than the idealized ones of eqns [8] and [13]. One also need not assume that the incident beam is perfectly collinear with the y -axis but can generalize the beam's direction (eqn [12]). This can be very useful in situations where the incident beam is not level (e.g., deflected upwards by a grazing-incidence mirror), but the entire diffractometer cannot be tilted. Several authors have worked out the equations for completely general diffractometer geometries.

Determining the Orientation Matrix

With the diffraction equation (eqn [14]) otherwise solved, the orientation matrix U must be determined; B must also be found if the sample's lattice parameters are not precisely known. Busing and Levy demonstrated several methods of determining U that result in a 1D set of solutions in diffractometer-angle space. To uniquely determine U , a constraint must be added; selection of constraints are discussed in the following section.

If the sample's lattice parameters are known, then two noncollinear orientation reflections, h_1 and h_2 , must be found to determine U . Then, in principle, solving the following equations for h_1 and h_2 will determine U :

$$h_{i\phi} = UBh_i \quad [15]$$

where $i = 1, 2$ and the $h_{i\phi}$ vectors are calculated from the observed angular positions of h_i . But in practice, experimental uncertainties prevent one U matrix from exactly satisfying eqn [15] for both $h_{1\phi}$ and $h_{2\phi}$. Errors can arise from effects such as mosaic spread, refraction, beam divergence, or mechanical imperfections in the diffractometer. Therefore, the following procedure is commonly used to determine U : $h_{1\phi}$, called the primary reflection, exactly satisfies eqn [15], but $h_{2\phi}$, as the secondary reflection, only determines the rotation of the coordinate system about $h_{1\phi}$. Exchanging h_1 and h_2 generally results in slightly different solutions for U . Generally, to minimize the effect of angular misalignment and achieve a more accurate solution of U , the orientation reflections should be at fairly high angles (high $|Q|$) and fairly far apart in angle (as a suggestion, the angle between h_1 and h_2 should be at least 40°). On the other hand, when a good alignment is not easily maintained, one could select orientation reflections that are close to each other and then probe only the nearby region of reciprocal space. Then, when another region is to be probed, a new set of orientation reflections can be chosen in the new region.

When the sample's lattice parameters are not known, the matrix UB must be determined; sometimes the UB matrix, rather than just U , is known as the orientation matrix. In the unknown lattice-parameter case, three non-coplanar reflections (h_1, h_2, h_3) with known (or assumed) Miller indices should be found that, with the selection of one constraint as discussed below, allows for a unique solution of UB in eqn [15]. With four or more reflections, a least-squares fitting method can be applied to eqn [15] to refine the lattice parameters. The resulting lattice parameters will not exactly reflect the symmetry of the crystal lattice but should be fairly close. For example, with a cubic crystal, the unit cell lengths should be nearly equal, and the angles should be within a few tenths of 90° . With a sufficiently large set of orientation reflections h_i , still other parameters may also be refined, such as a displacement of the crystal from the diffractometer's center of rotation.

Operating Modes

As mentioned above, the calculation of diffractometer angles for a given reciprocal-lattice point is under-determined, since reciprocal space is three-dimensional while a four-circle diffractometer has, obviously, four degrees of freedom. An additional constraint is needed that is usually achieved by freezing one angle at a certain value. In the case of a four-circle normal-incidence diffractometer, the detector angle 2θ is determined by the magnitude of the scattering vector Q ; a constraint cannot be placed on 2θ without restricting the range of accessible reciprocal space to a single magnitude of $|Q|$. Therefore, constraints in the four-circle Eulerian geometry should be applied only to a diffractometer's sample angle or to an appropriately defined azimuthal angle.

The simplest and perhaps most common four-circle mode is to constrain ω (see eqn [2]) at a fixed value. The constraint of $\omega = 0$ is called the symmetric or bisecting mode, since the incident and diffracted beams make the same angle to the plane of the χ circle; generally, this mode permits the greatest access to reciprocal space. Another mode based on sample angles is to constrain χ or φ to a fixed value; such a mode might be useful when a sample environmental cell (e.g., oven, cryostat, or vacuum chamber) has a small window that must be kept oriented to the incident beam, but is otherwise fairly limiting.

Another possible operating mode is to choose a zone, a plane of reciprocal space passing through the origin, as the scattering plane. A zone can be defined by two non-collinear Bragg points; appropriate values of χ and φ are then selected to place the two Bragg points in the scattering plane. This mode contains two constraints, that is, it freezes two sample angles. Thus, access to reciprocal space is reduced to a single plane, but data collection is simplified since the zone can be studied with movements of only 2θ and θ .

Instead of constraining a particular sample angle to a given value, one can also constrain the azimuthal rotation of the sample about the scattering vector. As shown in Figure 2b, ψ is the azimuthal rotation about Q . In defining ψ , a reference vector N must be chosen. N can point in any direction except parallel to Q , but is often a special direction for the sample, for example, the surface normal, a magnetic field direction, or the direction of polarization in a polar material. The definition of $\psi = 0^\circ$ is when N lies in the scattering plane; $\psi = 90^\circ$ when N lies in the plane defined by Q and the diffractometer's $\theta/2\theta$ axes. The constrained- ψ mode is particularly useful in surface diffraction when N is chosen to be the surface normal. Mochrie has shown how to calculate ψ for a given incident angle or exit angle, which provide particularly convenient modes for grazing-incidence or grazing-exit studies. The constraint of $\psi = 90^\circ$ sets the incident angle equal to the exit angle.

Equivalent Angle Settings

In addition to selection of an operating mode, other choices of angle must be made in the operation of a diffractometer. Although any angle can theoretically be rotated by 360° without changing anything, the axes of most diffractometers have limited ranges of motion and cannot rotate indefinitely. The diffractometer-control software must determine, for example, whether a rotation from -170 to $+170^\circ$ will be done with a motion of -20 or $+340^\circ$. Furthermore, symmetry operations make some sets of angle combinations equivalent. For example, for a given χ and φ , the pair of angles $(2\theta, \omega)$ are equivalent to $(-2\theta, \omega-180)$, but both settings may not be equally practical or accessible on a given diffractometer. In general, seven sets of angles can substitute for the set of $(2\theta, \theta, \chi, \varphi)$, although not all of these sets are compatible with all operating modes. A diffractometer-control program must, implicitly or explicitly, select one of these sets. A convenient choice is to select angles that fall within the allowed range as set by software limits.

Alternative Four-Circle Geometries

Kappa Geometry

Several types of four-circle diffractometer geometries exist in addition to the Eulerian geometry described above. Perhaps the most common is the “kappa” geometry, originally developed by Enraf–Nonius. As shown in Figure 3, the χ circle of the Eulerian geometry is replaced by a κ -axis, which is built on an arm at an angle of α_0 to the θ_κ axis; typically, α_0 is nominally 50° . The κ -axis rotates another arm with another angle of α_0 , upon which sits the φ_κ -axis. The “ κ ” subscripts on the θ_κ and φ_κ circles distinguish those circles of the kappa diffractometer from similar θ and φ circles of a standard Eulerian diffractometer, although not all systems of nomenclature make this explicit distinction. One could incorporate the rotation matrix of κ in deriving solutions to the diffraction equation (eqn [14]). However, it is often simpler to directly relate the kappa angles (θ_κ , κ , φ_κ) to the Eulerian angles (θ , χ , φ):

$$\begin{aligned}\theta &= \theta_\kappa - \cos(\kappa/2)/\cos(\chi/2) \\ \chi &= 2\arcsin[\sin(\kappa/2)\sin\alpha_0] \\ \phi &= \phi_\kappa - \cos(\kappa/2)/\cos(\chi/2)\end{aligned}\quad [16]$$

The relations in eqn [16] are straightforward to be included in the diffractometer-control software after an appropriate solution to eqn [14] is computed in Eulerian geometry, with the advantage of allowing users to operate a kappa diffractometer just as the more familiar Eulerian diffractometer is. In doing so, (θ , χ , φ) are called “pseudoangles,” whereas the physically present (θ_κ , κ , φ_κ) are called “real” angles.

The foremost advantage of a kappa-geometry diffractometer is the elimination of the χ circle. The primary weakness of Eulerian geometry is the limited mechanical perfection of the χ circle; any deviation from a perfect circle will, for example, increase the sphere of confusion. This issue is often exacerbated for diffractometers with an open or split χ circle. On the other hand, a closed χ circle blocks the incident or diffracted beam for some values of θ ; beam blockage is less of an issue with kappa geometry. A related advantage is the relative compactness of the κ arm compared to the χ circle, making kappa geometry popular for confined spaces or crowded experimental stations. One hypothetical drawback of the kappa geometry is its limited angular range. As seen in eqn [16], a kappa diffractometer whose κ -axis has a full range of $\pm 180^\circ$ emulates a Eulerian diffractometer with a maximum theoretical range of $\chi = \pm 2\alpha_0$ (i.e., typically $\pm 100^\circ$). This issue can be dealt with by selection of a suitable angular setting, as discussed above, and should not generally pose a problem. A practical caution is that the asymmetric shape of the kappa arm, as it folds and unfolds, makes it particularly vulnerable to collisions with nearby objects (e.g., the input flight path or the detector arm); care should be taken to properly set hardware and software limit switches such that collisions cannot occur in any potential angular configuration.

Four-Circle General-Inclination Geometries

Another class of diffractometers, known as general-inclination geometries, is distinct from the normal-incidence geometries in that it provides more than one degree of freedom to the detector. Such geometries can significantly increase the range of accessible reciprocal space in situations where the angular range is limited by a sample cell. In contrast to the normal-incidence geometry, the

Figure 3 Diagram of a four-circle kappa diffractometer. The angles are chosen to hold a sample at the same place as the Eulerian diffractometer shown in Figure 2b, via the relations given eqn [16].

scattering plane (containing K , K_0 , and Q) of the general-inclination geometry is no longer fixed; there is no simple one-to-one correspondence between the general-inclination and normal-incidence geometries such as that which exists between the Eulerian and kappa geometries. Since the position of the detector in a general-inclination geometry is a compound motion of several angles, the total scattering angle 2θ must be calculated, and cannot be simply read from one dial on the instrument. In this article, the convention that 2θ is the total scattering angle is followed. As such, only the normal-incidence geometry has a single circle that can be properly labeled 2θ , although many systems of nomenclature use 2θ as the label for one of the detector circles.

Several variations of four-circle inclined-geometry diffractometers have been developed, two of which are illustrated in Figure 4. For the “Z-axis” diffractometer (Figure 4a), the sample sits on the η -axis and the detector on the δ and γ -axes; all three axes then rotate about the α -axis. It may be noted that many Z-axis diffractometers call the sample axis θ (or ω); here, this axis is labeled as η to emphasize that it is not equivalent to the Eulerian θ -axis, since the η -axis is not orthogonal to the X-ray beam when $\alpha \neq 0$. The Z-axis geometry is particularly useful in holding heavy sample equipment such as vacuum chambers, as it minimizes motions that must be coupled through the sample chamber. The total scattering angle 2θ is given by

$$2\theta_{Z\text{-axis}} = \arccos(\cos \gamma \cos \delta \cos \alpha + \sin \alpha \sin \gamma) \quad [17]$$

Another example of inclined geometry is the “S2D2” diffractometer. As shown in Figure 4b, the S2D2 geometry is composed of two pairs of orthogonal axes: the sample rotates on η and μ , while the detector rotates on δ and ν . Indeed, the name “S2D2” is meant to indicate that this geometry has two degrees of freedom for the sample (“S2”) and two degrees of freedom for the detector (“D2”). In this nomenclature, the normal-incidence four-circle Eulerian and kappa diffractometers both have “S3D1” geometry. The Z-axis geometry does not exactly fit into this naming system, since one degree of freedom is shared between the sample and detector, but the designation (S1D2)*1 has been used, implying that a Z-axis diffractometer is an S1D2 (three-circle) diffractometer mounted upon a fourth circle. A practical advantage of the S2D2 geometry is the mechanical decoupling of the sample and detector motions, limiting the propagation of mechanical errors. The scattering angle of the S2D2 diffractometer is given by eqn [17] with γ set to zero:

$$2\theta_{S2D2} = \arccos(\cos \nu \cos \delta) \quad [18]$$

The orientation matrix U of a four-circle inclined geometry can be calculated in the same way as for the four-circle normal-incidence geometry case, and a mode with one constraint must be selected. The diffraction equations are similar to the normal-incidence case, but the appropriate rotation matrices for the sample and detector axes must be incorporated on both sides of eqn [14].

The Z-axis and S2D2 geometries are particularly useful for surface scattering when the surface normal is aligned parallel to the η -axis, since the angle of incidence is given simply by the diffractometer angle α or μ , respectively. However, sufficiently precise sample alignment is often not easy, especially in a vacuum environment, which leads naturally to the desire for additional degrees of freedom for the sample. Such diffractometer geometries are described in the next section.

Figure 4 Two examples of general-inclination four-circle diffractometers: (a) Z-axis geometry; (b) S2D2 geometry.

Five-Circle and Six-Circle Diffractometers

Representing the next level of complexity and flexibility, five- and six-circle diffractometer geometries all fall into the class of inclined geometries. In general, such diffractometers have been developed to provide better access to larger ranges of reciprocal space or to provide greater flexibility in sample positioning, given the constraints of a particular experiment.

Several varieties of five- and six-circle diffractometers have been constructed. The basic five-circle diffractometer could be characterized as a four-circle normal-incidence diffractometer (either Eulerian or kappa) with the θ -axis horizontal, mounted on a fifth rotation stage whose axis is vertical. The sample and detector motions are coupled by the fifth circle, so this five-circle geometry could be labeled (S3D1)*1. This five-circle diffractometer can be converted into a six-circle instrument by the addition of another vertical axis, upon which sit the sample circles (θ , χ , and φ); the entire diffractometer rotates on the bottommost axis. Alternatively, one could add the χ and φ circles of a Eulerian cradle (or the κ and φ_κ circles of a kappa arm) to an S2D2 diffractometer (Figure 4b); this geometry decouples the sample and detector motions and would thus be labeled S4D2. Another six-circle geometry is formed by adding a Eulerian cradle to a Z-axis diffractometer (Figure 4a); the sample and detector motions of this geometry are coupled through the α -axis.

While the additional degrees of freedom in five- and six-circle diffractometers provide much greater flexibility in operation, the degree of complexity in operation increases correspondingly. On a practical level, five- and six-circle diffractometers are generally quite large, with more (and heavier) counterweights than four-circle diffractometers. The large size and extra degrees of freedom increase the possibility of collisions and the damage that a collision can cause; hardware and software limits must be carefully set to avoid a collision in any potential angular configuration. More fundamentally, the choice of a mode becomes more complicated. Each additional degree of freedom (rotation axis) requires an additional constraint in the transformation between angle space and reciprocal space. Specifically, to uniquely determine the angle settings for a reciprocal lattice point, a five-circle or six-circle diffractometer requires, respectively, two or three constraints. The number of possible operating modes becomes correspondingly larger, and the geometry calculations supported by the diffractometer-control software also grow in complexity.

Although the modes of a five- or six-circle diffractometer require selection of several constraints, the constraints cannot be chosen arbitrarily. For example, one could not constrain two detector circles, since that would limit reciprocal-space access to a single magnitude of $|Q|$. In the case of surface diffraction, one could not choose both the incident angle and the exit angle since that would overconstrain the azimuthal angle; one could choose to make the incident and exit angles equal but could not select a specific value for both. In the particular case of S4D2 geometry, a system was developed by You to organize mode selection by categorizing the angles which could be subject to constraints. The three categories of angles are detector, azimuthal, and sample. A detector constraint would fix one of the angles upon which the detector rotates, or would fix the angle of Q or reference vector N with respect to the horizontal plane; for example, Q or N could be fixed to lie in the horizontal or vertical plane. Azimuthal constraints include fixing the incident or exit angle, or otherwise fixing the azimuthal angle ψ . Possible sample constraints include fixing a sample angle at a certain value or constraining it relative to another angle. The key to this method is that no more than one constraint may be placed on either detector angles or azimuthal angles; the remaining constraint(s) must be applied to sample angles. Both sets of data in Figure 1, for example, were collected on an S4D2 diffractometer with one detector constraint (fixed angle of N), one azimuthal constraint (fixed angle of incidence), and one sample constraint (η was fixed to be half of δ). One could also select one detector or azimuthal constraint and two sample constraints, or one could select three sample constraints.

The development of five- and six-circle diffractometers was driven by the need for flexibility in diffractometer operation, especially for access to the widest possible range of reciprocal space, given the experimental constraints. While some future advances in this technique may lie in the area of new diffractometer geometries, more critical needs lie in the area of improved data-collection efficiency. For example, many experiments may benefit from detectors with the sometimes-conflicting qualities of better resolution, larger dynamic ranges, or parallel data collection by use of 1D or 2D detectors. The overhead expense of motor motion can be reduced by the so-called trajectory or on-the-fly scanning: rather than collect data point by point, the diffractometer axes rotate continuously and the incoming data are binned into multichannel counters. In general, just as modern computers have made multicircle diffractometry viable as a regular research tool, increased automation will improve the efficiency in all steps of a diffraction experiment.

Acknowledgments

Data in Figure 1 were collected at the Advanced Photon Source beamline 7ID, in collaboration with R Clarke and C Cionca (Figure 1a), and M J Bedzyk and D M Goodner (Figure 1b). Use of the Advanced Photon Source was supported by the US Department of Energy, Office of Science, Basic Energy Sciences, under Contract No. W-31-109-ENG-38.

Introduction

When an electron is placed in solid material, it will scatter from the potential of the atoms. If the atoms are identical and ordered in a perfect lattice, the constructive interference compensates the scattering. In this case the eigenstates of the electron are plane-wave-like solutions, called Bloch waves. The Bloch states extend over the whole lattice and carry current. There are also regions in energy without eigenstates, corresponding to gaps. If the lattice of atoms is nearly perfect, the Bloch theorem is not mathematically valid anymore. However, a small imperfection could be treated as a weak perturbation that would mildly mix the Bloch states. With sufficient disorder, the transport becomes diffusive (ohmic). In this regime, a semiclassical picture of electrons bouncing from impurities might be sufficient to capture the essential physics. However, P.W. Anderson (1958) showed in his seminal paper that with sufficient amount of disorder, the electronic states at zero temperature do not diffuse but are localized in space. It means that a material that is metallic without defects would become an insulator at low temperatures when the amount of disorder is increased. Further, this case should not be mixed with the traditional insulators with a perfect lattice, where the Fermi energy happens to be within the gap region of energy.

'Classical' Treatment of Disorder

In actual solids, there are always static, chemical, and structural deviations from periodicity, located randomly within the solid; in other words, there is always disorder. The thermal vibrations of atoms (or ions), although dynamical in nature, can be treated for fast processes and high temperatures as additional sources of static disorder. However, at low temperatures, lattice vibrations and other dynamical processes lead to inelastic scatterings, which are clearly distinct from the elastic scatterings considered up to now; these inelastic scatterings are responsible for an energy uncertainty, ΔE , which in turn defines an inelastic dephasing time $\tau_\phi \sim \hbar/\Delta E$; for $t \gtrsim \tau_\phi$, the phase is randomized.

Disorder is crucial in determining important transport properties, such as electrical and thermal conductivities, magnetoresistances, photoconductivities, and metal–insulator transitions. Under normal conditions, the main role of disorder is to change the propagation of electrons (or more generally, of whatever carriers) from ballistic to diffusive; the latter involves a new characteristic quantity, the so-called transport mean free path, l , which is connected to the diffusion length $L_D = (D\tau)^{1/2}$ by the relation $L_D = l/\sqrt{d}$. D is the diffusion coefficient, $\tau = l/v$, v is the carrier velocity, and d is the space dimensionality. The transport mean free path, for low concentration, $n_s = N_s/V$, of scatterers is related to the transport cross section σ_{ti} of each scatterer by the relation

$$\frac{1}{l} = \frac{1}{V} \sum_{i=1}^{N_s} \sigma_{ti} \quad [1]$$

which means that over a length l , the N_s scatterers within the volume $V = Sl$ will intercept the whole cross section, S , of the incoming wave (i.e., $S = \sum_i \sigma_{ti}$).

[☆]Change History: June 2015. A. Harju carried out an overall improvement to the text. Most importantly, the role of P.W. Anderson is introduced.

The summation of σ_{ν} s in eqn [1] implies that interference effects have been omitted; thus the term ‘classical’ in the title of this subsection. Actually, a scattered wave from one scatterer can be scattered again by other scatterers; this is especially true when the σ_{ν} s are large and their concentration, n_s , is high. All these single and multiple scattered waves can, in principle, interfere with one another, possibly modifying the basic result in eqn [1]. The argument in support of eqn [1] is that constructive and destructive interference more or less cancel each other as a result of the interfering waves having random phase differences (associated with the random positions and phase shifts of the scatterers).

Weak Disorder and the Role of Interferences

Consider an electron initially ($t=0$) at the point r . The probability density amplitude, $A(t)$, to again find the electron at r , after time t , is given by $A(t) = \sum_{\nu} A_{\nu}(t)$, where the sum is over all directed path integrals, $A_{\nu} = \exp[(i/\hbar) \int_0^t L(r_{\nu}(t')) dt']$, starting and ending at r . The probability density, $dP(t)/d^3r$, to find the electron at r after time t is $dP/d^3r = |A(t)|^2 = \sum_{\nu} |A_{\nu}(t)|^2 + \sum_{\nu \neq \mu} A_{\nu}(t) A_{\mu}^*(t)$. Omitting the last double sum on the basis of random phases is equivalent to the approximation leading to eqn [1]. However, not all terms with $\mu \neq \nu$ have random phases; indeed, for each path $\mu = \bar{\nu}$, where $\bar{\nu}$ is the same as path ν but run in the opposite direction (the last equality stems from time-reversal symmetry), and consequently $\sum_{\gamma \neq \mu} A_{\gamma} A_{\mu}^* = \sum_{\gamma} A_{\gamma} A_{\bar{\gamma}}^* + \sum_{\mu \neq \gamma, \bar{\gamma}} A_{\gamma} A_{\mu}^*$. Thus, making the reasonable assumption that $\sum_{\mu \neq \nu, \bar{\nu}} A_{\nu} A_{\mu}^*$ is really zero because of random phases, one may come to the conclusion that dP/d^3r is twice as big as the classical diffusion would predict, since $\sum_{\gamma} A_{\gamma} A_{\bar{\gamma}}^* = \sum_{\gamma} |A_{\gamma}|^2$. Actually, $dP(t)/d^3r$ is less than twice as large because the equality $A\bar{\nu} = A_{\nu}$ is not valid for very long paths, whose length far exceeds the inelastic dephasing length $L_{\phi} \equiv (\tau_{\phi})^{1/2}$; for such long paths, repeated inelastic scattering destroys the phase equality of $A\bar{\nu}$ and A_{ν} . In any case, the conclusion is that interference effects make quantum diffusion slower than classical diffusion, and lead to a decrease of the diffusion coefficient and the electrical conductivity. This decrease is proportional to the integral $\int dt \sum_{\gamma} A_{\gamma} A_{\bar{\gamma}}^*$.

The latter can be estimated by taking into account that the paths which contribute are inside a tube of cross section λ^2 (or λ^{d-1} for a d -dimensional system, where λ is the wavelength) around the classical trajectory. Furthermore, the probability of returning is directly related to the probability of self-intersection of this orbital tube. Within time dt , the wave would move by νdt and would sweep a volume $dV = \lambda^{d-1} \nu dt$; hence, the probability of self-intersection during the time interval dt , after time t has elapsed, is equal to the ratio of the volume $dV = \lambda^{d-1} \nu dt$ over the total volume swept up to t ; the latter is of the order of $L_D^d = (Dt)^{d/2}$. Hence, the probability of self-intersection at any time between $t = \tau$ and $t = \tau_{\phi}$ is proportional to $\int_{\tau}^{\tau_{\phi}} dt \lambda^{d-1} \nu / (Dt)^{d/2}$. The elastic collision time, $\tau = l/\nu$, has been set as the lower limit because, for $t \ll \tau$, the motion is ballistic and the probability of self-intersection is zero; the inelastic dephasing time τ_{ϕ} is the upper limit since for $t \gtrsim \tau_{\phi}$, the phase equality of A_{ν} and $A\bar{\nu}$ is lost. Notice that at high temperatures, where $\tau_{\phi} \approx \tau$, the quantum corrections are negligible. On the other hand, for low temperatures, where $\tau_{\phi} \gg \tau$, there is an appreciable increase in the probability, p , of returning to the initial point and consequently an appreciable correction, $\delta\sigma = \sigma - \sigma_0$, to the classical conductivity, σ_0 , as a result of interference effects:

$$\delta\sigma \sim -p \sim 1 - \left(\frac{\tau_{\phi}}{\tau}\right)^{1/2} \approx -\left(\frac{\tau_{\phi}}{\tau}\right)^{1/2} = -\frac{L_{\phi}}{L_D} \quad (1D \text{ systems}) \quad [2a]$$

$$\delta\sigma \sim -p \sim -\frac{\lambda}{L_D} \ln \frac{\tau_{\phi}}{\tau} = -\frac{2\lambda}{L_D} \ln \frac{L_{\phi}}{L_D} \quad (2D \text{ systems}) \quad [2b]$$

$$\delta\sigma \sim -p \sim -\frac{\lambda^2}{L_D^2} \left[1 - \left(\frac{\tau}{\tau_{\phi}}\right)^{1/2}\right] = -\frac{\lambda^2}{L_D^2} \left(1 - \frac{L_D}{L_{\phi}}\right) \approx 0 \quad (3D \text{ systems}) \quad [2c]$$

The above formulas are valid when the disorder is weak, so that $|\delta\sigma|$ is considerably smaller than σ_0 , since otherwise, one could end up with negative conductivity $\sigma = \sigma_0 + \delta\sigma$. The condition $|\delta\sigma| \ll \sigma_0$ implies that $\lambda \ll L_D$, which in turn means that under the present conditions, $\delta\sigma$ is negligible for 3D systems. On the other hand, for 1D and 2D systems, $\delta\sigma$ can become appreciable when $L_{\phi} \gg L_D$; furthermore, since τ_{ϕ} is proportional to T^{-1} for 2D and $T^{-2/3}$ for 1D systems, and for very low temperatures, T , it follows that σ for $d=1$ and $d=2$ decreases with decreasing T . Such a T -dependence suggests an insulating behavior as $T \rightarrow 0$ K, and consequently, the nonexistence of one- and two-dimensional metallic behavior. In other words, the possibility is raised that in 1D and 2D systems, as $L_{\phi} \rightarrow \infty$, the conductivity may become zero, no matter how weak the disorder is. The possibility of $\sigma \rightarrow 0$ as $L_{\phi} \rightarrow \infty$ may be realized even in 3D systems when the disorder is strong enough, so that $\lambda \gtrsim L_D$. This question is taken up again in the next subsection, in which formulas [2a]–[2c] are generalized to the strong disorder case.

This subsection is concluded by pointing out that the presence of a magnetic field, B , breaks the time-reversal symmetry, and as a result, breaks the equality $A_{\nu} = A\bar{\nu}$, and consequently, reduces the magnitude of $|\delta\sigma|$, and thus, tends to restore the classical behavior. Actually, the magnetic field adds a term $q\mathbf{A} \cdot \mathbf{v}$ to the Lagrangian, where q is the charge of carriers ($-e$ for electrons), and $\mathbf{A}$ is the vector potential such that $\mathbf{B} = \nabla \times \mathbf{A}$. So the closed path integrals, $A_{\nu}, A\bar{\nu}$, in the presence of B , acquire an extra phase, that is $A_{\nu} = A_{\nu 0} \exp(i\phi_{\nu}), A\bar{\nu} = A_{\nu 0} \exp(-i\phi_{\nu})$, where $\phi_{\nu} = q\phi_{\nu}/\hbar$, and ϕ_{ν} is the magnetic flux through the closed path. As a result $A_{\gamma} A_{\bar{\gamma}}^* + A_{\bar{\gamma}} A_{\gamma}^* = 2|A_{\nu 0}|^2 \cos(2\phi_{\gamma})$, instead of $2|A_{\nu 0}|^2$ as in the case $B=0$. This implies a periodic variation of the conductance as a function of the applied magnetic field if ϕ_{ν} is a constant independent of ν . Indeed, this phenomenon has been observed in cylindrical tubes of cross section S with very thin walls, and with the magnetic field parallel to the axis of the tube. The configuration is such that $\phi_{\nu} = nBS$, where $n = 1, 2, \dots$. Because L_{ϕ}^2 is not much larger than S , the dominant contribution comes from $n=1$ and the

Figure 1 Various mesoscopic wires. (a) Simple quantum wire. (b) The gate voltage, V_G , creates a restriction which gradually, by changing V_G , leads to the 1D limit. (c) Four probe ring configuration which splits the current to the two semicircular paths. (d and e) Four probe configurations differing by the presence of the ring in case (e). The cross sections of the wires are $\sim 10^3 \text{ nm}^2$, and their length $\sim \mu\text{m}$.

conductance, G , varies as $\delta G \sim \cos(2eBS/\hbar)$; this is the so-called $h/2e$ Aharonov–Bohm effect. In ring configurations, such as in Figure 1(c), where the conduction paths are between diametrically opposite points, the variation of the conductance, δG , is proportional to $\cos(eBS/\hbar)$; this is the so-called h/e Aharonov–Bohm effect. Notice that the Aharonov–Bohm effects can provide an operational definition of the length L_ϕ , since for lengths $L \gtrsim L_\phi$, the characteristic conductance oscillations gradually disappear. In thin wires, such as in Figures 1(d) and 1(e), the oscillatory magnetic field dependence of the conductance is more complicated as shown in Figure 2. It must be pointed out that these oscillations are reproducible (for the same system) and that their size is universal and $\sim e^2/\pi\hbar$. Furthermore, the conductance in the system of Figure 1(d) is different from that in the system of Figure 1(e),

Figure 2 Electrical conductance versus applied magnetic field for the configuration of **Figure 1(d)** (left) and for that of **Figure 1(e)** (right). in spite of the classical current carrying paths being identical in the two configurations; this shows the wave nature of electronic propagation, the non-negligible role of interference effects associated with the existence of the ring in **Figure 1(e)**, and the nonlocal nature of the current–electric field relation.

Disorder, Density of States, and Wave Functions

Three-Dimensional Systems

In **Figure 3(a)**, the density of states (DOS) of a band associated with the s -level of identical atoms placed periodically in a simple cubic lattice is shown; the bandwidth is $12|V_2|$, where V_2 is the matrix element transferring electrons between two neighboring atoms. Disorder is introduced (**Figures 3(b)–3(d)**) by assuming that the s -levels of atoms are independent random variables possessing a Gaussian distribution of standard deviation w . The effects of the disorder are the following: (1) The analytical singularities shown in **Figure 3(a)** disappear. (2) The bandwidth increases as the band edges $\pm E_B^{(0)}$ move to new positions $\pm E_B$, where $E_B - E_B^{(0)} = c_1 w^2 / |V_2|$ ($c_1 \approx 0.25$ in the present case). (3) Besides this widening of the band, tails in the DOS, $\rho(E)$, appear which are of exponential nature, $\rho(E) \sim \exp(-|E|/E_0)$ for $E_B \lesssim |E|$, where $E_0 = c_2 w^2 / |V_2|$ ($c_2 \approx 0.12$ in the present case); these tails give rise to tails in the optical absorption of semiconductors for $\hbar\omega$ less than the gap (Urbach tails). (4) Two characteristic energies, $\pm E_c$, termed mobility edges, appear at which the nature of the eigenstates changes from propagating (or extended) to non-propagating (or localized, shaded regions in **Figures 3(b)–3(d)**). The localized eigenstates are trapped either around a cluster of atoms or around a single atom whose s -energy level is much different than the average. For low disorder ($w \lesssim 2.5|V_2|$), the mobility edges follow the band edges closely, $|E_B| - |E_c| \sim w^4 / |V_2|^3$. As the disorder increases, the mobility edges start moving toward the center of the band, and eventually they merge together making all eigenstates of the band localized; this is known as the Anderson transition (in the present case, this transition occurs when $w \approx 6.2|V_2|$).

For weak disorders (e.g., **Figure 3(b)**), the states near the center of the band are quasi-Bloch characterized by the band index, j , the wave vector, $\mathbf{k}$, and the mean free path, which is connected to the phase $\phi(\mathbf{r})$ of the eigenfunction through the relation $\langle \exp[i\phi(\mathbf{r}) - i\phi(0)] \rangle = \exp(-r/2l')$, where the symbol $\langle \rangle$ denotes the average value over all random variables. The mean free path l' satisfies eqn [1] with σ_i instead of σ_{ii} . As one moves from the center of the band toward the mobility edges, the amplitude of the eigenstates develops ever increasing fluctuations, both in magnitude and spatial extent up to a maximum length, ξ ; for distances, r , such that $a \ll r \lesssim \xi$, the eigenfunctions exhibit a statistically self-similar, fractal, behavior (a is the lattice spacing). As $|E| \rightarrow |E_c|$, ξ blows up, $\xi \rightarrow A'/(|E_c| - |E|)^\gamma$, where γ has been estimated to be 1.58 (in the absence of a magnetic field) and 1.43 (in the presence of a magnetic field). On the localized sides of the spectrum, the eigenfunctions, $\psi(\mathbf{r})$, decay exponentially on the average, that is, $\langle |\psi(\mathbf{r})| \rangle_g \sim \exp(-r/L_c)$, as $r \rightarrow \infty$, where $\langle |\psi(\mathbf{r})| \rangle_g \equiv \exp[\langle \ln |\psi(\mathbf{r})| \rangle]$, and L_c is the so-called localization length. For distances, r , such that $a \ll r \lesssim L_c$, the eigenfunctions exhibit fluctuations of statistically self-similar, fractal nature. As $|E| \rightarrow |E_c|$, L_c blows up: $L_c \rightarrow A'/(|E| - |E_c|)^\gamma$.

The contribution of a band to the conductivity, $\sigma(T)$, is given by $\sigma(T) = \int dE \sigma(E, T) (-\partial f / \partial E)$, where $f(E)$ is the Fermi–Dirac distribution, $\sigma(E, T)$ is proportional to the DOS $\rho(E)$ and the mobility $\mu(E)$ at E . The conductivity $\sigma(E, T)$ for a finite cube of length L at $T = 0$ K is given by

$$\sigma(E, 0) = \frac{e^2}{h} \left(\frac{0.066}{\xi} + \frac{A_1}{L} \right) \quad [3]$$

for E in the extended region (A_1 is ~ 0.05), $\sigma(E, 0) \sim \exp(-2L/L_c)$ in the localized regime, and for $L_c \ll L$. Actually, L , besides the length of the specimen, can be of any number of upper cut-off lengths such as L_ϕ or $R_B = (\hbar_d / eB)^{1/2}$, the cyclotron radius in the presence of a magnetic field, or $L_w = (D/\omega)^{1/2}$, the diffusion length in the presence of an AC field of frequency ω , etc. In the presence

Figure 3 The density of states (DOS) of a band associated with the s -level of atoms placed periodically in a simple cubic lattice. The s -level of each atom is an independent random variable of Gaussian probability distribution with zero-average value and standard deviation equal to w , which goes from zero (case (a)) to $6.5|V_2|$ (case (d)). The bandwidth at $w=0$ is $12|V_2|$. Shaded regions correspond to localized eigenstates.

of all these upper cut-off lengths, L in the above formulas should be replaced by an effective length, $\tilde{L}$, probably of the form $\tilde{L}^{-2} = c_1 L^{-2} + c_2 L_\phi^{-2} + c_3 L_\omega^{-2} + c_4 R_B^{-2} + \dots$, where the weights c_i are of the order of unity.

Two-Dimensional Systems

2D systems of electrons trapped at the interface of Si/SiO₂ or GaAs/Al_xGa_{1-x}As, are in a borderline as far as localization properties are concerned. In the absence of magnetic forces, all eigenstates are localized, no matter how weak the disorder is (exceptions do exist). In the presence of magnetic forces, the situation is qualitatively similar to that shown in Figures 3(b)–3(d) with an extremely narrow region of extended states at the center of the band. This picture has been employed to interpret the so-called integral quantum hall effect (IQHE), where as the Fermi level moves in the localized regime, the Hall resistance does not change until it enters the extended regime and a rather abrupt step is exhibited.

In the absence of magnetic forces, the localization length at E is related to the mean free path $l(E)$: $L_c(E) \simeq 2.7l(E) \exp\{S(E)l(E)/4\}$, where $S(E)$ is the length of the line in k -space satisfying the equation $E_k = E$. The conductivity $\sigma(E, 0)$ is given by an approximate interpolation formula involving $\tilde{L}$ and L_c as well as a length $r_0 \simeq \tilde{c}l$. In the limit $\tilde{L} \ll L_c$,

$$\sigma \approx \sigma_0 - \frac{e^2}{\pi^2 \hbar} \ln \frac{\tilde{L}}{r_0} \quad [4]$$

while for $L_c \ll \tilde{L}$, $\sigma = (2\sigma_0 \tilde{L}/L_c) \exp(-2\tilde{L}/L_c)$. Equation [4] is similar to eqn [2b] and is known as a weak localization correction. For $\tilde{L} \simeq R_B$, eqn [4] gives $\delta\sigma \equiv \sigma(B) - \sigma(0) = (e^2/2\pi^2 \hbar) \ln[1 + (eL_\phi^2 B/1.78\hbar c)]$, that is a negative magnetoresistance, $\delta R/R \simeq -\delta\sigma/\sigma$, as

Figure 4 Experimental data (solid squares) and theoretical results (continuous lines) for the relative magnetoresistance $-\Delta R/R$, in a two-dimensional sample of electronic concentration $n = 1.6 \times 10^{11} \text{ cm}^{-2}$ and mobility $\mu = 27000 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$. (Reproduced from Choi, K.K., *et al.*, 1987. Dephasing time and one-dimensional localization of two-dimensional electrons in GaAs/Al_xGa_{1-x}As heterostructures. *Physical Review B* 36, 7751.)

shown in Figure 4. For $L \simeq L_\phi \sim T^{-1/2}$, the above formulas for the conductivity show that $\sigma \rightarrow 0$ as $T \rightarrow 0 \text{ K}$. Notice, however, that electron–electron interactions produce a similar temperature dependence. Nevertheless, recent experiments at very low temperatures, in very clean interfaces GaAs/Al_xGa_{1-x}As or Si/SiO₂, have shown that $\sigma(T)$ stops decreasing and starts increasing with decreasing temperatures.

A second two-dimensional material of relevance here is graphene, a two-dimensional allotrope of carbon. The weak localization in graphene is more complicated than for the two-dimensional electron gas discussed above, as the Berry phase π in a closed trajectory can convert the weak localization to weak antilocalization, see Tikhonenko *et al.* (2009). For strong short-range disorder, strong localization is expected.

One-Dimensional and Quasi-One-Dimensional Systems

For 1D systems, such as the one shown in Figure 1(b), all eigenstates are localized, no matter how small the disorder is (exceptions do exist); the localization length is proportional to the mean free path, $L_c = cl$, where the coefficient c equals 4 for not-so-strong a disorder. The conductivity, σ , is given by $\sigma = (e^2 \tilde{L} / \pi \hbar) / [\exp(2\tilde{L}/L_c) - 1]$. Thus in the limit $\tilde{L} \ll L_c$, $\sigma = (e^2 L_c / 2\pi \hbar) - (e^2 \tilde{L} / 2\pi \hbar)$; the first term gives the classical result $\sigma = 2e^2 l / \pi \hbar$, since $L_c = 4l$, while the second is linear in $\tilde{L}$ as in eqn [2a]. Taking into account that the conductance G in 1D equals to $\sigma / \tilde{L}$ and that the geometrically averaged transmission coefficient, T , equals to $\exp(-2\tilde{L}/L_c)$, the formula for σ can be recast as $G = (e^2 / \pi \hbar) T / (1 - T)$. However, a direct calculation of G gives $G = (e^2 / \pi \hbar) T$. This discrepancy is due to the fact that the first formula gives the conductance of the wire *per se* without taking into account the two contact resistances $2R_c = \pi \hbar / e^2$, and it requires a four-probe measurement for its determination; on the contrary, the result $G = (e^2 / \pi \hbar) T$ is the outcome of a two-probe measurement and it includes the contact resistances, so that $1/G = 2R_c + R_w = (\pi \hbar / e^2) + (\pi \hbar / e^2) [(1 - T)/T] = (\pi \hbar / e^2) / T$. In the presence of M coupled parallel to 1D channels in the limit where $\tilde{L} \ll l$ and $T \simeq 1$, the two-probe measurement will give $G = (e^2 / \pi \hbar) M$ in agreement with the experimental results in Figure 5. The importance of the above formulas lies in their capability to be generalized to a multiterminal system; each terminal, i , is in contact with a reservoir at electrochemical potential $\mu_i = -|e|V_i$, and feeds the system with a net current I_i .

$$I_i = \frac{e^2}{\pi \hbar} \sum_j T_{i \leftarrow j} (V_i - V_j) \quad [5]$$

Equation [5] is very useful in treating many mesoscopic systems, such as quantum dots exhibiting the phenomenon Coulomb blockade.

Level Statistics

Localized eigenstates belonging to neighboring energy levels of a very large system are, in general, far away from one another and hence, they have negligible overlap and as a result, negligible level repulsion. On the contrary, extended eigenstates always overlap, and thus always exhibit level repulsion. Hence, the probability distribution of the separation of two consecutive energy levels

Figure 5 The electrical conductance of the configuration shown in Figure 1(b) vs. the gate voltage, V_g . The step-like dependence on V_g according to the formula $G = (e^2/\pi h)M$, $M = 1, 2, \dots$, is shown. For $V_g < -2$ V, the 1D limit $M = 1$ has been reached. (Reproduced from van Wees, B.J., *et al.*, 1988. Quantized conductance of point contacts in a two-dimensional electron gas. *Physical Review Letters* 60, 848.)

(which can be obtained numerically) is quite different for localized and extended eigenstates. This difference is an efficient way for determining regions of localized and extended states.

Transfer Matrix Techniques

A transfer matrix, t_{12} , propagates the general solution of the wave equation from point x_1 to point x_2 along 1D and quasi-1D systems. By multiplying transfer matrices, $t_{0L} = t_{12}t_{23} \dots t_{NL}$, the solution at one end ($x=0$) can be connected to the solution at the other end ($x=L$). For disordered quasi-1D systems, the eigenvalues of t_{0L} come in pairs $(\mu_i, \bar{\mu}_i)$, such that $\mu_i \rightarrow \exp(L/L_{ci})$ and $\bar{\mu}_i \rightarrow \exp(-L/L_{ci})$ as $L \rightarrow \infty$, where $\pm L_{ci}^{-1}$ are the so-called Lyapunov exponents. The longest L_{ci} , L_c , determines the transmission coefficient, T , of the quasi-1D system of length L as $T = (-2L/L_c)$. By considering quasi-1D strips of M coupled channels arranged in a plane, or wires of square cross section with M^2 channels, $L_c(M)$ can be determined numerically; by employing a scaling property, the limit $M \rightarrow \infty$ can be taken, which determines L_c for the 2D case ($L_c = \lim_{M \rightarrow \infty} L_c(M)$), and both L_c (when $L_c(M)$ converges as $M \rightarrow \infty$) and ξ (when $L_c(M) \sim M^2/\xi$) for the 3D case.

Scaling Approach

In the model considered in Figure 3, the only relevant parameter is the dimensionless ratio $w/|V_2|$. Then a cluster of p neighboring atoms of length $L_1 = p^{1/d}a$ (where a is the lattice spacing) is examined and one may attempt to define a single dimensionless ratio, Q_1 , which would play for the cluster the same role as $w/|V_2|$ plays for each atom. By repeating the rescaling n times, where n eventually approaches infinity, one finds that $Q_n = (\hbar/e^2)G$, where G is the conductance of a d -dimensional ‘cube’ of linear dimension $L = p^{n/d}a$. Since $Q_n \equiv Q(L)$ is the only relevant parameter, the occurrence or not of localization depends on whether $Q(L)$ tends to infinity or to zero respectively, as $L \rightarrow \infty$. To find this limit, the logarithmic derivative $\beta = d \ln Q/d \ln L$, which depends on the parameter Q , is defined. In the limit $Q \rightarrow \infty$, the classical behavior is approached, which gives that $Q \sim G \sim L^{d-2}$; hence $\beta \rightarrow d-2$, that is, negative for $d < 2$ and positive for $d > 2$. Assuming that β is a monotonically increasing function of Q , one can conclude that in the limit $L \rightarrow \infty$, $G \rightarrow 0$ for $d < 2$. For $d > 2$, $G \rightarrow \infty$ as $L \rightarrow \infty$ (in the region $\beta > 0$), and $G \rightarrow 0$ as $L \rightarrow \infty$ (in the region $\beta < 0$).

Potential Well Analogy

More sophisticated approximate analytical approaches for the calculation of σ permit one, under certain conditions, to map the localization question to that of an effective d -dimensional potential well (in the absence of magnetic forces) of depth $V_0(E) \sim [\sigma_0(E)]^{-1} [I(E)]^{-d}$ and linear extent $a \sim l(E)$. If this effective potential well sustains a bound state of decay length $L_c(E)$, then the states at E are localized with localization length equal to $L_c(E)$. If the effective potential well exhibits a resonance in the cross section at $E_r(E)$, then the eigenstates at E are extended with a length ξ given by $E_r(E) = \hbar^2/2m\xi^2(E)$, $\xi \gg l$. Using the fact that a potential well, no matter how shallow, always sustains a bound state for $d \ll 2$, while it must exceed a critical value of $V_0 a^2$ to sustain a bound state for $d = 3$, the basic picture presented before is recaptured, before including the expressions for the localization length in 1D and 2D

systems. Furthermore, by employing the critical value of $V_0 a^2$, one finds that localized states appear in 3D systems, when the product $lk \lesssim 0.85$ or $l/\lambda \lesssim 0.14$; this is the so-called Ioffe–Regel criterion.

Other Realizations

There is also evidence of Anderson localization of light, see Segev (2010), and cold atom gases, see Modugno (2010).

Band Model and Optical Properties

An insulator, also called a dielectric, is a material that resists the flow of electric current. An insulating material has atoms with tightly bonded valence electrons. These materials are used in parts of electrical equipment, also called insulators or insulation, intended to support or separate electrical conductors without passing current through themselves. Some materials such as glass, paper, or Teflon are very good electrical insulators.

Insulators are characterized, and contradistinguished from metals, by the existence of a forbidden energy band of finite width, a band gap, between the highest filled band (the valence band) and the lowest empty band (conduction band). The existence of a band gap can be confirmed by the optical transparency, that is, a vanishing absorption constant, up to a finite energy a little below the band gap ε_g , except in the lower energy region where the absorption due to lattice vibrations may arise.

The energy difference between the first absorption peak and the band gap ε_g , from where the continuous spectrum of band-to-band transitions starts, is due to the Coulomb binding energy between the excited electron in the conduction band and the positive hole left behind in the valence band, a typical example of ‘configuration interaction’ – a step beyond the one-electron approximation of the band model – or of ‘final state interaction’ in the optical spectrum. This bound electron–hole pair is called ‘exciton,’ which means a quantum of excitation.

Spin–Orbit Mott insulators

Mott insulators are the byproduct of strong electron correlations. Many of them are based on 3d transition metals (V2O3, cuprates, etc.) with narrow, half-filled bands. This situation favors insulating states via the Mott electron localization mechanism. In iridium oxides (iridates) 5d orbitals are more extended spatially than 3d orbitals leading to a strong reduction in the Coulombic repulsion. Furthermore taking into account the splitting of bands due to crystal field effects leads to the highest occupied electron band being far away from half-filling. Therefore taking into account both of the above effects one would expect the Mott states to be less favorable in the iridates. However, it turns out that many iridates are in fact insulators, and the currently accepted physical picture is that they realize a new form of insulator, so called spin-orbit Mott insulator (Kim *et al.*, 2008), where the spin–orbit interaction is essential in splitting the electron bands and opening up an insulating gap. The layered perovskite Sr₂IrO₄ is certainly the most studied case and is becoming a reference example. There are many questions that remain open about the properties of a SO-Mott insulator including its full spectrum of magnetic/electronic excitations which include magnons, spin-orbital excitons and interband transitions. Another key issue is the effect of charge doping. In many Mott insulators doping has been shown to bring about new exotic phases, such as high-temperature superconductivity in the layered cuprates.

Theoretical ideas (Wang and Senthil, 2011) have been put forward that high-temperature superconductivity of a different kind to the one in the cuprates could occur in doped pinorbits in Mott insulators, such as Sr₂IrO₄. Experimentally there are only a few reports (Ge *et al.*, 2011) so far on successful doping of Sr₂IrO₄ or Ba₂IrO₄. While these two materials apparently only differ in a local

tilt of the IrO_6 octahedra, only the Ba one becomes metallic under pressure. Therefore the understanding of how to dope iridates and what happens in this case to SO Mott insulators is currently one of the priority challenges in the field.

Topological Kondo Insulators

Kondo insulators are a particularly simple type of a heavy fermion material where highly renormalized f-electrons, hybridized with conduction electrons, form a completely filled band of quasi particles with excitation gaps in the millivolt range. While these materials are strongly interacting electron systems, their excitations and their ground-states can be regarded as adiabatically connected to non-interacting band insulators.

It has been recently shown that most (time-reversal invariant) band-insulators can be classified by the topological structure of their ground-state wave functions (Fu *et al.*, 2007).

One of the dramatic consequences of this discovery is the existence of a new class of 'topological' band-insulators in which strong SO coupling leads to a ground-state that is topologically non-trivial, giving rise to gapless surface excitations. It has been recently proposed (Alexandrov *et al.*, 2013) that the 'old' heavy fermion materials, longtime studied in the context of quantum criticality, represent indeed strong candidates to host new SO-driven topological phases, where the strong correlation may stabilize 'heavy' Dirac quasi particles.

Exciton Model and the Optical Spectrum Near the Absorption Edge

The relative motion of the electron and the positive hole with orbital radius larger than the interatomic distance can be described in the effective mass approximation, and if their effective masses m_e and m_h and hence the reduced mass $m_r = (m_e^{-1} + m_h^{-1})^{-1}$ are isotropic, the binding energies form a hydrogen-like series: $Bn = Ry_{\text{ex}}/n^2$ ($n = 1, 2, \dots$), $Ry_{\text{ex}} = (m_r/m)(\epsilon_0/\epsilon_e)^2$ where $Ry = 13.6$ eV is the Rydberg energy, m the electron mass in vacuum, ϵ_0 the dielectric constant of vacuum, and ϵ_e the electronic dielectric constant $\epsilon(\omega)$ at $\hbar\omega \sim O(Ry_{\text{ex}}) < \epsilon_g$ which is contributed only from electronic transitions except when B_n is as small as the phonon energies. The exciton radius is given by $a_n = a_{\text{ex}} n^2$, $a_{\text{ex}} = (m/m_r)(\epsilon_e/\epsilon_0)a_H$ where $a_H = 0.052$ nm is the orbital radius of the electron in the ground state of a hydrogen atom. This Wannier model of an exciton is valid for insulators with relatively small bandgap (less than a few eV) and hence with large values of (ϵ_e/ϵ_0) and a_{ex}/a_H of the order of 10. In insulators with a larger bandgap, the exciton radius is smaller than or comparable with the interatomic (intermolecular) distance, and the Frenkel model of intra-atomic (intramolecular) excitation (as in rare gas solids and aromatic molecular crystals), or the model of charge transfer to neighboring atoms (from an anion to neighboring cations as in ionic crystals) is more appropriate at least for an exciton in its ground state ($n = 1$).

In the Wannier model, the matrix element of the optical transition is given as a product of that for the inter band transition and the amplitude of the hydrogen-like wave function $F_n(R_m)$ of the relative motion at the origin $R_m = 0$ (probability amplitude that the electron and the hole are found on the same site), which is non-vanishing only for the s-like states ($\ell = 0$ where ℓ is the angular momentum). Thus, the intensity of the ns exciton line at $\hbar\omega = E_n = \epsilon_g - B_n$ in the absorption spectrum is proportional to the square of the above amplitude, namely to n^{-3} ($n = 1, 2, \dots$) as known in the hydrogen atom. Noting that the product of the intensity and the number density of states $|dE_n/dn|^{-1} \propto n^3$ is independent of n and hence of energy $\hbar\omega$, one finds that the absorption spectra consisting of higher exciton lines overlapping with each other (due to their finite widths) tends to a plateau of constant height as $n \rightarrow \infty$. It can also be shown analytically that this asymptotic height is in exact accordance with that of the continuous spectrum of band-to-band transition with the Coulomb-enhancement factor $(\hbar\omega - \epsilon_g)^{-1/2}$ which cancels out the density of states effect $(\hbar\omega - \epsilon_g)^{+1/2}$. The resulting absorption spectrum around the band edge is shown schematically in Figure 1(a) where the n -dependence of the width γ_n of discrete lines does not affect the above mentioned continuity.

In the case that the matrix element of band-to-band transition vanishes at the band edge ϵ_g due to a reason of symmetries of band wave functions, one has to consider its values above the edge. Correspondingly, one has to use the gradient $\nabla_R F_n(R_m)$ of the

Figure 1 The effect of Coulomb interaction on the fundamental absorption edge. The broken lines represent the interband absorption edge without the Coulomb effect. hydrogen wave function at the origin, which is nonvanishing only for the p -like states $\ell=1$. Thus, np exciton lines ($n=2,3,\dots$) appear at $\hbar\omega=E_n=\epsilon_g-B_n$ of the absorption spectrum with intensities proportional to $(n^{-3}-n^{-5})$, with $n=1$ missing. It can be shown, as before, that the broadened exciton lines asymptotically merge smoothly (inclusive of the finite slope extrapolating to the $n=1$ position) to the continuous spectra of the Coulomb enhanced band-to-band transition around ϵ_g . The absorption spectra in this case of the forbidden band edge is schematically shown in Figure 1(b). The intensity of the absorption spectra is smaller than that in the allowed band edge case mentioned above by a factor $(a/a_{\text{ex}})^2$, where a is the interatomic distance. Absorption spectra in alkali halides and cuprous oxides shown in Figures 2(a) and 2(b) belong to the cases (a) and (b), respectively, of Figure 1.

Insulators with small band gaps become intrinsic semiconductors except at low temperatures. The existence of thermally excited free carriers causes a metallic screening of a long-range electron-hole Coulomb interaction into a short-range one, thus affecting the inter band optical spectra in such a way that the discrete exciton lines merge into the continuous spectra of inter band transition as temperature rises. Moreover, the free carriers give rise to their own optical absorption (intra band optical transition) in the infrared region.

Dipole–Dipole Interaction Contributing to the Translational Motion of an Exciton

As a composite particle consisting of an electron in the conduction band with effective mass m_e and a positive hole in the valence band with effective mass m_h , the exciton has effective mass $m_{\text{ex}}=m_e+m_h$ and translational kinetic energy $\hbar^2 K^2/2m_{\text{ex}}$ near the bottom of the exciton band. Finite bandwidths of the valence, conduction, and hence exciton bands are due to the overlaps of wave functions between neighboring atoms.

The width of the exciton band is contributed by another type of interaction energy, the dipole–dipole interaction. Take the Frenkel exciton in which this interaction predominates, and consider how the intra-atomic excitation at the n th atom is transferred to the m th site. Consider the state $\Phi_n=\phi_p(r_n-R_n)\prod_{\ell(\neq n)}\phi_s(r_\ell-R_\ell)$ where all atoms are in the s -like ground state except the n th atom which is in a p -like excited state. The excitation transfers to the m th atom through the matrix element

$$H_{nm}\equiv(\Phi_n,H\Phi_m)=\int\int dr_n dr_m \phi_p(r_n-R_n)\phi_s(r_m-R_m)\times v_{nm}\phi_s(r_n-R_n)\phi_p(r_m-R_m)$$

where H denotes the total Hamiltonian of the system consisting of N atoms with one electron per atom. Note that due to the orthogonality of atomic wave functions ϕ_s and ϕ_p and the neglect of overlaps of wave functions between different atoms, only

Figure 2 (a) Fundamental absorption spectrum of KCl crystal 10 K. Reproduced with permission from Tomiki, T., 1969. *Journal of the Physical Society of Japan* 26, 738. the Coulomb interaction $v_{nm} = e^2/4\pi\epsilon_0 |r_n - r_m|$ remains among the total Hamiltonian H . Due to the same reasons, one can take only the lowest dipole-dipole terms in the multipole expansion of the long-range Coulomb interaction, namely $H_{nm} = (\mathbf{m}^2/R_{nm}^3 - 3(\mathbf{m} \cdot \mathbf{R}_{nm})^2/R_{nm}^5)/4\pi\epsilon_0 \equiv D(\mathbf{R}_{nm})$, where $\mathbf{m} \equiv \int d\mathbf{r} \phi_p(\mathbf{r})(-e\mathbf{r})\phi_s(\mathbf{r})$ is the transition dipole moment. The Hamiltonian H is diagonalized with the wave function of the Frenkel exciton given by $\Psi_K^{(e)} = N^{-1/2} \sum_n \exp(i\mathbf{K} \cdot \mathbf{R}_n) \Phi_n$, namely $H_{KK'} = \delta_{KK'} E_K^{(e)}$, with diagonal energy being $E_K^{(e)} = (\Psi_K^{(e)}, H \Psi_K^{(e)}) = E^{(g)} + \epsilon + D_K$ where $E^{(g)}$ is the ground-state energy of the entire system, $\epsilon = \epsilon_p - \epsilon_s$ the atomic excitation energy in the crystal and $D_K \equiv \sum_{n \neq 0} D(\mathbf{R}_n) \exp(-i\mathbf{K} \cdot \mathbf{R}_n)$. Thus, the dipole-dipole interaction contributes to the K -dependence of the exciton energy.

One must be careful in summing up the long-range dipole-dipole interaction $D(\mathbf{R}_n) \propto R_n^{-3}$ because of the slow convergence, especially when K is much smaller than the reciprocal of the interatomic distance a . Dividing the summation into the inner region $R_n < R_c$ and the outer region $R_n > R_c$ where R_c is chosen so as $a \ll R_c \ll K^{-1}$, and replacing the latter summation by integration, one obtains $D_K \equiv \sum_{n \neq 0}^{R_n < R_c} D(\mathbf{R}_n) - (N_0/3\epsilon_0)[m^2 - 3(\mathbf{m} \cdot \mathbf{K})^2/K^2]$, which is singular at $\mathbf{K} = 0$ since it tends to different values depending on the direction in which $\mathbf{K}$ approaches 0. In a typical case that each atom is situated in the environment of cubic symmetry, the first summation vanishes. One has triply degenerate atomic p -states p_x, p_y , and p_z so that one has a 3×3 matrix of the K -dependent part: $(D_K)_{ij} = -(N_0\mu^2/3\epsilon_0)[\delta_{ij} - 3K_i K_j/2]$. It is diagonalized by taking the coordinate system with the z -axis along the direction of $\mathbf{k}$. In fact, one obtains a longitudinal wave $\mathbf{m} \parallel \mathbf{K}$ with energy $(D_K)_{33} = (2/3)(N_0\mu^2/\epsilon_0)$, and two transverse waves $\mathbf{m} \perp \mathbf{K}$ with energy $(D_K)_{11} = (D_K)_{22} = -(1/3)(N_0\mu^2/\epsilon_0)$. Their energy difference, $N_0\mu^2/\epsilon_0$, agrees with $\hbar$ times the longitudinal-transverse splitting $D_{11} = \omega_1 - \omega_t$ of polarization waves which originates from the depolarizing field. Under the coexistence of many oscillators, ϵ_0 is to be replaced by the residual dielectric constant ϵ_j' which is contributed by the oscillators other than the one (j) under consideration. Note that this dielectric constant is different from ϵ_e , which governed the electron-hole relative motion.

The Effect of Spin and the Interplay of Exchange and Spin-Orbit Interactions

To be more realistic, one must consider the electron spin in addition to its orbital motion. Each atomic state characterized by (n, l, m) is doubly degenerate with up and down spins, $s = \pm 1/2$. The simplest closed shell atom consists of two ns electrons with configuration $(ns)^2$, and its optically allowed excited state consists of the configuration $(ns)(np)$. The two electrons in the excited state can have either antiparallel (as in the ground state) or parallel spins, with energy difference $2\Delta_{\text{exch}} (> 0)$ where $\Delta_{\text{exch}} = \int \int d\mathbf{r} d\mathbf{r}' \phi_p(\mathbf{r})\phi_s(\mathbf{r})(e^2/4\pi\epsilon_0)|\mathbf{r} - \mathbf{r}'|^{-1}\phi_s(\mathbf{r}')\phi_p(\mathbf{r}')$ is the exchange energy. The singlet state is above the triplet state because one is concerned with the e - h (instead of the e - e) system. The optical transition to the triplet excited state is forbidden because of its total spin state $S = 1$ ($S \equiv s_1 + s_2$) different from that of the ground state $S = 0$. Noting that Δ_{exch} is the special case ($n = m$) of H_{nm} in the preceding section and that the dipole-dipole interactions vanish for the triplet state but are to be multiplied by 2 for the singlet state (because two electrons participate), one can incorporate the exchange and dipolar energy into a single form, $2\delta_{S,0}|F_n(0)|^2[\Delta_{\text{exch}} + D_K]$, where multiplication by the squared amplitude of the wave function of e - h relative motion at the origin is required only where the interaction remains in the Wannier exciton. The total energy of the Wannier exciton with the principal quantum number n , spin quantum number S , and translational wave vector $\mathbf{K}$ is then given by $E_{n,S}(\mathbf{K}) = \epsilon_g - B_n + \hbar^2 K^2/2m_{\text{ex}} + 2\delta_{S,0}|F_n(0)|^2[\Delta_{\text{exch}} + D_K]$. Another term to be considered is the spin-orbit interaction $H_{s.o.} = \lambda \mathbf{l} \cdot \mathbf{s}$. One can diagonalize it together with the total angular momentum $j = l + s$ by making use of the identity $2\mathbf{l} \cdot \mathbf{s} = (j^2 - l^2 - s^2) = j(j+1) - 1.2 - (1/2) \cdot (3/2)$. Thus, the atomic state with $\ell = 1$ are split into $j = 3/2$ and $j = 1/2$ with spin-orbit energies $+\lambda/3$ and $-\lambda/3$, respectively. According to this quasi-atomic model, the valence band of alkali halide which consists of p -orbitals of halogen is split to the upper ($j_v = 3/2$) and lower ($j_v = 1/2$) branches while the conduction band consisting of s -orbital of alkali is not split ($j_v = 1/2$ only). Hence, the absorption edge of band-to-band transition appears at $\epsilon_g - \lambda/3$ and $\epsilon_g + 2\lambda/3$ with the intensity ratio 2:1 reflecting the degeneracy $2j_v + 1$. This j - j coupling scheme is no more valid for exciton lines because of finite exchange-dipolar interaction, $\Delta_n \equiv 2\delta_{S,0}|F_n(0)|^2[\Delta_{\text{exch}} + D_0]$ mentioned above. As Δ_n/λ increases the intensity ratio decreases, tending to 0 since the lower exciton state tends to a pure spin-triplet ($S = 1$) which is optically forbidden (L - S coupling). In materials with small spin-orbit coupling constants as are realized with light atom constituents, the triplet exciton is optically almost forbidden. The continuous change from the j - j to L - S and again to j - j coupling schemes has been observed in the alloy system $\text{CuCl}_{1-x}\text{Br}_x$ in which λ varies continuously from negative to positive values with Δ_{exch} staying always small as composition x varies from 0 to 1, as is shown in Figure 3. The L - S coupling scheme is realized only around the composition x where λ changes sign, the j - j coupling scheme with intensity ratio 1:2 and 2:1 is observed on its left and right sides, respectively.

The quasi-atomic model mentioned above has been improved to the crystalline field model in which the symmetry of the crystal is fully taken into account. The anisotropic exchange energy introduced thereby as an independent material parameter has in fact been observed in some materials.

Participation of Phonons in the Electronic Excitation

The wave vector of a photon with energy enough for the electronic excitation across a band gap of 10 eV is $\sim 10^8 \text{ m}^{-1}$ which is much smaller than the reciprocal lattice $\sim 10^{10} \text{ m}^{-1}$. One can thus assume that the wave vector (pseudo or crystal momentum divided by $\hbar$) is conserved in the optical transition, namely $\mathbf{k}_c - \mathbf{k}_v = 0$ or $\mathbf{K}_{\text{ex}} = 0$. In addition, it has been tacitly assumed so far that the bottom of the conduction band and the top of the valence band are at the origin, $\mathbf{k}_c^m = 0$ and $\mathbf{k}_v^m = 0$, which, however, is not always the case. If one or both of them are not at the origin, the absorption edge of band-to-band transition appears around the indirect gap $\epsilon_g = \epsilon_c(\mathbf{k}_c^m) - \epsilon_v(\mathbf{k}_v^m)$, but with the participation of phonons with wave vector $\mathbf{K} = \mathbf{k}_{\text{id}}$ and $\omega_s(\mathbf{k})$ to satisfy the conservation of the wave

Figure 3 (a) Observed energies, and (b) intensity ratio of $Z_{1,2}$ and Z_3 excitons in mixed crystal: $\text{CuCl}_{1-x}\text{Br}_x$ as functions of the concentration x . Reproduced with permission from Kato, Y., Yu, C.I., Goto, T., 1970. Journal of the Physical Society of Japan 28, 104.

vector. Hence, the exact absorption edge appears at $\varepsilon_g - B'_n \pm \hbar\omega_s(\pm k_{id})$ according as a phonon is absorbed or emitted, where B'_n is the binding energy of the exciton formed at $K=k_{id}$ and $\omega_s(k)$ is the circular frequency of the s th mode lattice vibration with wave vector K . The absorption spectrum rises with the square root of energy from each edge reflecting the density of states of the exciton band, with the intensity proportional to the square of the indirect exciton–phonon interaction matrix element and the temperature dependent factor $\bar{n}_s$ and $\bar{n}_s + 1$ for absorption and emission of a phonon, respectively, where $\bar{n}_s = [\exp\{\hbar\omega_s(\pm k_{id})/k_B T\} - 1]^{-1}$ is the thermal average of the number of phonons. Such indirect exciton edges are observed in germanium and silicon ($k_c^m \neq 0$), silver halides ($k_v^m \neq 0$), and thallous halides ($0 \neq k_c^m \neq k_v^m \neq 0$). Similar phonon-mediated exciton edge arises even when $k_c^m = k_v^m = 0$, provided the exciton transition matrix element vanishes at $K_{ex} = 0$, as is realized with the $1s$ exciton in Cu_2O (see Figure 2(b)).

The widths γ of direct exciton absorption peaks, introduced phenomenologically as damping constants of oscillators, are microscopically attributed to the rate τ^{-1} of scattering of the optically created exciton $K_{ex} = 0$ to $K_{ex} \neq 0$ by absorbing or emitting a wave number conserving phonon, which is of the same origin as the indirect exciton transition mentioned above. An indirect exciton absorption band is, therefore, supposed to be the tail part of the broadened peaks of a direct exciton. As a second-order process, the $K=0$ exciton is the intermediate state which is resonant and non-resonant to the incident photon in the direct and indirect transitions, respectively.

In fact, one can incorporate both aspects in a unified expression for a multicomponent exciton absorption spectrum. For a multiband scheme of excitons with energy $E_{\lambda K}$, one can write the spectral line shape as the sum of asymmetric Lorentzians: $F(E) = \sum_{\lambda} \bar{f}_{\lambda} \pi^{-1} [\bar{\Gamma}_{\lambda 0} + \bar{A}_{\lambda}(E - \bar{E}_{\lambda 0})] / [(E - \bar{E}_{\lambda 0})^2 + \bar{\Gamma}_{\lambda 0}^2]$ which is in accordance with the result of the classical model of damped oscillators ($\hbar\gamma_{\lambda} \leftrightarrow \bar{\Gamma}_{\lambda 0}$) for the direct exciton peaks, except for the asymmetry terms with $\bar{A}_{\lambda}$ (the degree of asymmetry) in the numerator, and the fact that the quantities crowned with bars are the renormalized (in the phonon field) quantities dependent on a variable E , the photon energy (though not shown explicitly). The shape of the indirect absorption edge is contained implicitly in the

functional form of the width $\bar{\Gamma}_{\lambda 0}(E)$, which is proportional to the combined density of states of excitons and phonons in the final state of indirect transition. The asymmetry term $\bar{A}_{\lambda}(E - \bar{E}_{\lambda 0})$ in the numerator originates from the interference of the direct exciton peak λ with its background continuum of indirect exciton transitions to other exciton bands $\lambda' (\neq \lambda)$ – a solid-state version of the Fano effect well known in atomic spectroscopy. Such multicomponent asymmetric Lorentzian peaks have, in fact, been observed as shown in **Figure 2(b)**. The asymmetry here is due to the interference of the direct exciton peak with the background continuum of phonon-assisted optical transition to the $1s$ exciton band to which the direct transition is forbidden. Phonon sidebands of the direct exciton peak (as are observed in some ionic crystals) are also contained implicitly in the functional form of $\bar{\Gamma}_{\lambda 0}(E)$.

Absorption Bands of Extrinsic Origin below the Band gap

While (chemically) pure and (physically) perfect insulators are transparent in the spectral region below the first exciton peak (in the direct band gap case), impure or imperfect insulators have various absorption bands due to the electronic transitions at impurity (guest) atoms or point defects of a lattice. The localized electron(s) is subject to a strong interaction with phonons (stronger than the mobile exciton is) particularly when its orbital radius is comparable with the lattice constant, and once excited, it causes significant displacements of nearby atoms to their new equilibrium positions (lattice relaxation). From this ‘relaxed excited state,’ the electron returns to the ground state emitting a photon (luminescence) or non-radiatively. The peak of the emission band is displaced from that of the absorption band (Stokes shift), both bands being more like Gaussian shapes as can be described by the configuration coordinate model. Examples are Tl -like atoms in alkali halides which are known as phosphorescence centers of high efficiency and the F-centers (an electron captured at an anion vacancy) in alkali halides which are subject to a variety of photochemical reactions resulting in the color changes of the crystal.

The impurities and imperfections sometimes give rise to bound excitons as can be confirmed by the optical absorption bands just below the intrinsic exciton absorption peaks. For example, the α and β absorption bands in alkali halides correspond to exciton formation around an anion vacancy and an F-center, respectively. Shallow bound excitons, as are realized at donors in direct gap semiconductors (such as CdS), have large oscillator strengths of the order of the number of host atoms covered by their extended wave functions, the effect known as ‘giant oscillator strength.’

Intrinsic Photoluminescence and Its Correlation with the Urbach Rule

The optically created exciton will be thermalized around the bottom of the exciton band from where it will emit a photon with energy smaller (in the indirect case) than or equal (in the direct case) to the absorption edge. In the direct case, the exciton is gradually converted into a photon during its thermalization through the polariton bottleneck. In any case, the emission spectrum from this ‘mobile exciton’ is a sharp line.

In some materials, the exciton becomes self-trapped by the lattice distortion caused by itself. The emission spectrum of this selftrapped exciton is a broad Gaussian with a significant Stokes shift from the exciton absorption peak (direct gap case) or edge (indirect case), similar to the localized center mentioned before. In the configuration coordinate model, the self-trapped state is separated by a potential barrier from the free or mobile state, and which of them is more stable depends on whether the exciton–phonon coupling constant g , a material constant, is greater or smaller than a critical value g_c .

In contrast to different behaviors of the emission spectrum in the weak and strong coupling cases, the line shape of the exciton absorption band varies continuously as a function of g . For instance, the low energy tail of the exciton absorption spectrum in many insulators has been found to obey the Urbach rule: $\exp[-\sigma(E'_0 - E)/k_B T]$ except at low temperatures where E'_0 is the convergence point of semi-logarithmically plotted line contours at various temperatures T , and the steepness coefficient σ is the material constant. This exponential tail has been ascribed to momentarily localized exciton states under a fluctuating field of lattice vibrations, with σ being given by a constant (different values for direct and indirect gap cases) times g^{-1} . While empirical values of σ and g derived therefrom are rather evenly distributed over a variety of insulating materials, the observed emission spectrum of the exciton is distinctly different according as g is smaller ($\rightarrow$ sharp line almost resonant to the absorption peak in the direct gap case) or larger ($\rightarrow$ broadband with a significant Stokes shift) than the critical value g_c in accordance with the theoretical prediction from the observed value of σ .

Optical Excitation of Inner Shell Electrons

Synchrotron radiation has facilitated the spectroscopic studies over a vast energy range extending up to the X-ray, corresponding to electronic transitions from different inner atomic states (much deeper than the outermost orbital state responsible for the valence band) to the empty conduction band. Below the ionization continuum of each inner state, there appear exciton lines as in the valence band excitation. However, the exciton here can be viewed as a localized excitation since the width of the energy band formed by the inner atomic state is negligibly small. Moreover, the positive hole in the inner state is subject to decay processes such as (1) radiative recombination, and (2) Auger recombination with an electron in the upper filled band (inclusive of the valence band) which are the main causes of a lifetime broadening of the exciton line, except in shallow inner bands (next below the valence band)

Figure 4 Typical dispersion of dielectric constant $\epsilon(\omega)$ of an ionic crystal. At frequencies far higher than those of optical phonons but a little below the bandgap, dispersion appears due to excitons associated with the valence band hole. At even higher frequencies, dispersions appear due to excitons associated with the inner shell holes. Reproduced with permission from Toyozawa, Y., 2003. *Optical Processes in Solids*. Cambridge: Cambridge University Press. © Cambridge University Press.

in some materials in which (1) is insignificant and (2) is impossible because of insufficient energy of electronic recombination against the ionization of valence electrons. Whether the optical spectrum belongs to the band edge allowed or forbidden type, depends on the symmetry of the inner atomic state. The electron–hole exchange energy with its possible interplay with spin–orbit interaction appears here in the same way as before.

Typical dielectric dispersion in the entire ω -region of an ionic crystal is shown schematically in **Figure 4**, in the idealistic situation of no damping (vanishing line width).

Introduction

The structural properties of the ruthenium oxides are mainly governed by the strong octahedral-site preference of the Ru(IV) ion; in the Ru–O phase diagram, RuO_2 is the only stable oxide. However, in the presence of counter cations that lower the energy of the top of the O-2 p bands, as in the double perovskite structure of $\text{A}_2(\text{Ln(III)Ru(V)})\text{O}_6$, the Ru(V) oxidation state can be realized. Moreover, in doped ruthenates, both the Ru(V)/Ru(IV) and the Ru(IV)/Ru(III) redox couples may be accessed.

The electronic properties of the ruthenium oxides are governed by the occupancy and orbital ordering of the Ru-4d states. Strong bonding of the Ru to oxygen results in an octahedral-site low-spin Ru(IV): t^4e^0 (Mullikan notation) outer-electron configuration in orbitals of 4d symmetry; the xy, (yz ± izx) t orbitals π -bond to the oxygen and the ($x^2 - y^2$), ($3z^2 - r^2$) e orbitals σ -bond. The cubic-field splitting of the t and e energies quenches the orbital angular momentum of quantum number L having $m_l = \pm 2$, but not that having $m_l = \pm 1$ of the (yz ± izx) orbitals. Therefore, a strong intraatomic spin–orbit coupling $\lambda(\mathbf{L} \cdot \mathbf{S})$ of a localized Ru(IV): t^4e^0 configuration is not quenched where the site symmetry orders the minority-spin 4d electron into the (yz ± izx) orbitals. On the other hand, strong Ru–O π bonding creates Ru–O–Ru interatomic interactions that can be strong enough to render the 4d electrons itinerant, which suppresses the localized spin–orbit coupling. The ARuO_3 perovskites with A = Ca, Sr, Ba, and Pb illustrate a crossover from localized to itinerant 4d electronic behavior and the influence of strong spin–orbit coupling where the intraatomic 4d electron–electron interactions compete with the interatomic Ru–O–Ru interactions between the 4d electrons. In the rutile structure of RuO_2 , orbital ordering fills the c-axis Ru(IV)-4d orbitals, which elongates the c axis; and the Ru–O–Ru π -bond interactions give metallic conductivity associated with a half-filled π^* band. RuO_2 is a catalyst for the oxygen-evolution reaction of an air electrode in an electrochemical cell.

The ruthenates containing other cations can be classified according to their structure into seven categories: perovskites, post-perovskites, Ruddlesden–Popper phases, hexagonal perovskite polytypes, pyrochlores, quasi-2D SrRu_2O_6 , and 1D Ln_3RuO_7 .

Ruthenate Perovskites and Post-Perovskites

The ideal AMO_3 perovskite structure, **Figure 3(a)**, consists of a cubic framework of corner-shared $\text{MO}_{6/2}$ octahedra with a larger A cation in the center of the framework. The $\text{MO}_{6/2}$ octahedra of the MO_3 framework may be rotated cooperatively to enhance the A–O bonding if the size of the A cation gives a geometric tolerance factor $t = (\text{A} - \text{O}) / [\sqrt{2}(\text{B} - \text{O})] < 1$; (A–O) and (M–O) are the equilibrium bond lengths. This structural flexibility allows stabilization of the perovskite system $\text{Sr}_{1-x}\text{Ca}_x\text{RuO}_3$ having a $t < 1$ in which the cooperative rotations of the $\text{RuO}_{6/2}$ octahedra are primarily around the cubic $[1 - 1 \ 0]$ axis, **Figure 1(b)**, to give an orthorhombic structure; in space group $Pnma$, the rotation axis is the orthorhombic a axis. However, the site rotations also induce site distortions (Zhou and Goodenough, 2005, 2008) in which the O–Ru–O bond lengths within the (001) planes alternate short and long; and as t approaches $t = 1$, the Ru–O–Ru bond angle subtending the rotation axis decreases from 90° to render the orthorhombic structure pseudocubic in SrRuO_3 (Lee *et al.*, 2013). For $t > 1$, the 180° Ru–O–Ru bonds of the cubic structure are stretched until, in BaRuO_3 , an hexagonal polytype structure is stabilized. In addition, the O-2 P_π orbitals of the cubic framework σ -bond with the A cations, and the competition between A–O σ bonding and Ru–O π bonding with the same O-2 P_π orbital modifies the strength of the Ru–O–Ru interactions as well as the bending from 180° of the Ru–O–Ru interactions. The competition

between intraatomic $\lambda(\mathbf{L} \bullet \mathbf{S})$ interactions and interatomic interactions of the minority-spin electrons is nearly balanced in SrRuO_3 , but the interatomic Ru-O-Ru interactions are weakened relative to the intraatomic $\lambda(\mathbf{L} \bullet \mathbf{S})$ interactions in CaRuO_3 . The transport properties of CaRuO_3 and SrRuO_3 perovskites are similar; they both exhibit bad-metal behavior (Figure 2) as a result of interatomic Ru-O-Ru interactions. Nevertheless, the magnetic properties of these oxides are very different: SrRuO_3 is ferromagnetic with a T_c of 165 K, whereas CaRuO_3 has been described for a long time as a paramagnetic metal involving antiferromagnetic interactions and is now believed by several authors to be nearly ferromagnetic, as supported by NMR observations. The different behavior of SrRuO_3 compared to CaRuO_3 is also observed; its $\rho(T)$ curve (Figure 2) shows a Fisher–Langer type anomaly at T_c . The highly correlated nature of the 4d-electron band in these perovskites is also confirmed by studies of their solid solution $\text{Sr}_{1-x}\text{Ca}_x\text{RuO}_3$. The peculiar magnetic behavior of CaRuO_3 , and the fact that it sits on the verge of a ferromagnetic instability is also supported by studies, which show that the substitution of Ti(IV) for Ru(IV) in this phase induces ferromagnetism at a low Ti level (2%).

By taking advantage of the high-pressure technique developed in the area of geosciences, the perovskite structure of BaRuO_3 can be stabilized. At atmosphere pressure, BaRuO_3 with $t > 1$ crystallizes in the 9 R polytype. High pressure is needed to reduce the tolerance factor t at the synthesis temperature. The high-pressure cubic phase of BaRuO_3 (Figure 1 (a)) stabilized at 18 GPa, is quenchable to ambient condition (Jin *et al.*, 2008). Two series of solid solutions $\text{Ca}_{1-x}\text{Sr}_x\text{RuO}_3$ and $\text{Sr}_{1-x}\text{Ba}_x\text{RuO}_3$ make it possible to map out T_c versus the averaged A cation size of the perovskite ruthenates. The maximum T_c is found for SrRuO_3 . However, the size variance effect introduced in the solid solution alters the curve of T_c versus $\langle r_A \rangle$. After correcting for the size variance effect, the data of T_c^0 versus $\langle r_A \rangle$ can be fit with a parabolic curve. The new phase diagram of Figure 3(a) reveals important information: (1) T_c is extremely sensitive to the change of lattice parameters; (2) the optimum T_c occurs in the ARuO_3 with $t \approx 1$; (3) while T_c decreases on both sides of the dome, the temperature dependence of magnetization gives distinctly different behavior as T_c is approached in the paramagnetic phase. All samples in the $\text{Sr}_{1-x}\text{Ba}_x\text{RuO}_3$ series show a typical Curie–Weiss behavior of $\chi(T)$ (Figure 3(c)). In contrast, the concave curvature of inverse paramagnetic susceptibility versus T in $\text{Ca}_{1-x}\text{Sr}_x\text{RuO}_3$ (Figure 3(b)) as T_c is approached from higher temperatures, resembles that of a Griffiths phase. This observation indicates that the suppression of magnetism in Ca rich $\text{Ca}_{1-x}\text{Sr}_x\text{RuO}_3$ is caused by a dilution with a non-magnetic phase. The local distortion at Ru sites in CaRuO_3 supports preserving the orbital angular momentum and $\lambda(\mathbf{L} \bullet \mathbf{S})$ orders the possible moment parallel to the c axis, which is orthogonal to the magnetic easy axis found in SrRuO_3 . The strong intraatomic spin–orbit coupling competes with the interatomic spin–spin interaction, which results in a non-magnetic ground state. A non-linear curve of inverse χ versus T of CaRuO_3 supports the argument of a strong spin–orbit coupling. In $\text{Sr}_{1-x}\text{Ba}_x\text{RuO}_3$, T_c decreases with x due to a bandwidth broadening. Suppression of T_c in BaRuO_3 can be made under high pressure; the ferromagnetic transition ends up with a quantum critical point (Zhou *et al.*, 2008).

PbRuO_3 prepared at ambient pressure has an oxygen deficient pyrochlore structure. Perovskite PbRuO_3 and the solid solution $\text{Sr}_{1-x}\text{Pb}_x\text{RuO}_3$ have been added into the $Pnma$ perovskite family by using high-pressure synthesis. The paramagnetic metal PbRuO_3 undergoes an unusual metal–metal transition at $T_s \approx 90$ K (Cheng *et al.*, 2009) to the orthorhombic $Imma$ phase in which an orbital ordering has been detected by neutron diffraction (Kimber *et al.*, 2009). The ferromagnetism of SrRuO_3 is progressively suppressed with Pb substitution in $\text{Sr}_{1-x}\text{Pb}_x\text{RuO}_3$ (Figure 4). On the PbRuO_3 side, the structural transition at T_s vanishes sharply with Sr substitution. T_s of PbRuO_3 can also be suppressed by applying a pressure of 5 GPa (Kusmartseva, *et al.*, 2013). At 30 GPa and room temperature, pressure induces a first-order structural transition to a highly distorted perovskite structure with the $Pbn/2$ space group (Figure 1(c)). A hybridization between the Ru:4d and Pb: 6s/6p leads to an unprecedentedly short Pb-Ru bond length in the perovskite structure (Cheng *et al.*, 2013).

The family of A-site ordered perovskites $\text{CaCu}_3\text{M}_4\text{O}_{12}$ ($M=\text{Ti, Cr, Mn, Ge, Sn, Ru, Ir, Pt}$) has grown quickly helped by high-pressure synthesis. Most of the A-site ordered perovskites are insulators. Metallic $\text{CaCu}_3\text{Ru}_4\text{O}_{12}$ crystallizes in a cubic structure with $a \approx 7.42 \text{ \AA}$ and $Im\bar{3}$ (No.204) space group, which consists of 3D corner-shared RuO_6 octahedra and Cu in co-planar sites. Due to the strong hybridization between Cu:3d and Ru:4d, $\text{CaCu}_3\text{Ru}_4\text{O}_{12}$ has become well-known for its heavy Fermion behavior and a Kondo-like effect. The valence on the Cu site can be changed by substituting Na, La, or their combination for Ca. **Figure 5** shows the relationship between the lattice parameters and the formal valence on the Cu site in $\text{ACu}_3\text{Ru}_4\text{O}_{12}$ ($A=\text{Na, Ca, La}$).

The perovskite CaRuO_3 can be converted into the post-perovskite structure (**Figure 1(d)**) at $P=23 \text{ GPa}$ and 980°C (Kojitani *et al.*, 2007). A post-perovskite structure consists of layered octahedra in which the $\text{RuO}_{6/2}$ octahedra are corner-shared on the c axis and edge-shared on the a axis. The post-perovskite CaRuO_3 is an insulator and exhibits a complicated temperature dependence of magnetic susceptibility; a broad hump at 450 K indicates a quasi-1D magnetic coupling and the Néel temperature occurs at 270 K. Like the perovskite CaRuO_3 , the local structural distortion at Ru sites orders the 4d-orbital occupancy so as to preserve the orbital angular momentum.

Besides, the Ru(IV) perovskites, a series of perovskites containing Ru(V) with the generic formulation A_2LnRuO_6 have been reported for $A=\text{Ca, Sr, or Ba}$ and $\text{Ln}=\text{La, Nd, Y, Ho, Lu, or Er}$. The crystal symmetry of these phases is often monoclinic ($P2_1/n$, with $a \sim b \sim a_c \sqrt{2}$, $c \sim 2a_c$, $\beta \sim 90.2^\circ$) and more rarely cubic ($Fm\bar{3}m$ $a \sim 2a_c$). All these oxides exhibit a 1:1 ordering between Ru(V) and Ln(III) or Ca(II) on the octahedral sites. Thus, in this structural type (**Figure 6**), one $\text{RuO}_{6/2}$ octahedron alternates with one $\text{LnO}_{6/2}$ octahedron along the three crystallographic directions. In all these compounds, the Ru(V) lattice is antiferromagnetic at low temperature with T_N values ranging from 26 to 40 K. Most of them exhibit an A-type antiferromagnetic structure at low temperature (**Figure 7(a)**), except $\text{Ba}_2\text{LaRuO}_6$, which belongs to the third type (**Figure 7(b)**). Moreover, the lanthanide cations may be involved

in the long-range antiferromagnetic order depending on their nature, as is illustrated, for example, for $\text{Sr}_2\text{ErRuO}_6$ (Figure 7(c)), which consists of two interpenetrating A-type antiferromagnetic sublattices on Ru(V) and Er^{3+} sites, respectively. High-temperature magnetic susceptibility measurements, carried out on Ba_2YRuO_6 , $\text{Ba}_2\text{LuRuO}_6$, and $\text{Sr}_2\text{LuRuO}_6$, suggest that the Ru(V) d-electrons may be itinerant rather than localized. Such a feature may result from a direct overlap of the neighboring Ru orbitals via Ru-O-O-Ru interactions. Perovskites A_2MRuO_6 involving a disorder of ruthenium and of a transition element M over the same octahedral sites have also been synthesized for $\text{M} = \text{Ni}, \text{Co}, \text{Fe}, \text{Cu}$. This site disorder is indeed the case for the compounds Sr_2MRuO_6 ($\text{M} = \text{Fe}, \text{Co}$), BaLaMRuO_6 ($\text{M} = \text{Ni}, \text{Co}$), and SrLaCoRuO_6 , all of which exhibit a monoclinic symmetry, either $\text{I}2/\text{c}$ or $\text{I}2/\text{m}$ or $\text{P}2_1/\text{n}$, with $a \sim b \sim a_c\sqrt{2}c \sim 2a_c$, and $\beta \sim 90.1^\circ$, except BaLaNiRuO_6 which is triclinic. These oxides exhibit a complex magnetic behavior, because two alioelectronic cations are distributed randomly over the octahedral sites. This situation often results in a spin-glass behavior as shown from the magnetic susceptibility curves of BaLaCoRuO_6 (Figure 8(a)), and of $\text{Sr}_2\text{FeRuO}_6$ (Figure 8(b)) which exhibit a cusp around 50 and 40 K, respectively. This behavior is significantly different from that of the double perovskites BaLaZnRuO_6 and BaLaMgRuO_6 , which exhibit an A-type antiferromagnetic ordering at low temperature; the Zn^{2+} and Mg^{2+} ions have no net spin.

Ruddlesden–Popper (RP) Ruthenates

The RP phases $A_{n+1}Ru_nO_{3n+1}$ with $A = \text{Ca}$ or Sr have single CaO or SrO rock-salt phases separating n layers of ARuO_3 perovskite structure. These structures allow monitoring of the evolution of electronic properties with the thickness of the perovskite layers. Ca_2RuO_4 and Sr_2RuO_4 represent the first member $n = 1$ of the RP series; their structure (Figure 9(a)) consists of single perovskite layers ‘ SrRuO_3 ’ or ‘ CaRuO_3 ’ intergrown with single rock-salt layers ‘ SrO ’ or ‘ CaO .’ In this structure, the Ru–O–Ru interactions are 2D rather than 3D, which reduces the π^* bandwidth associated with interatomic Ru–O–Ru interactions. These quasi-two-dimensional ruthenates exhibit different physical properties due to the different distortions of their structure. Ca_2RuO_4 exhibits a metal–insulator (MI) transition at $T_{\text{MI}} = 357 \text{ K}$ (Figure 10(a)). This Mott insulator is antiferromagnetic below $T_N = 110 \text{ K}$. In contrast, Sr_2RuO_4 is a p-wave superconductor below $T_c = 1.5 \text{ K}$ (Mackenzie and Maeno, 2003) and is paramagnetic above this temperature with a tendency toward ferromagnetism. A study of the system $\text{Ca}_{2-x}\text{Sr}_x\text{RuO}_3$ has shown that the system changes successively with decreasing x : from $x = 2$ where it is a nonmagnetic Fermi liquid, to a ferromagnetic metal for $x = 0.5$, to an antiferromagnetically correlated metal for $0.2 < x < 0.5$, and to an antiferromagnetic insulator for $x < 0.2$. Neutron powder diffraction studies demonstrate that the magnetic state changes are associated with structural transitions as shown in the phase diagram of Figure 11. Based on structural distortions, a magnetic phase diagram can be calculated that demonstrates the rotation and the tilting of the RuO_6 octahedra being responsible for the ferro- and antiferromagnetism, respectively. The substitution of La^{3+} for Ca^{2+} in Ca_2RuO_4 shows that doping with very small amounts of lanthanum lowers the MI transition dramatically down to 100 K and, simultaneously, the resistivity at low temperature can be decreased by several orders of magnitude (Figure 10(a)). Concomitantly, ferromagnetism is induced in the material (Figure 10(b)). The Curie temperature can reach up to 100 K , but it remains lower than T_{MI} , suggesting that the metal–insulator transition is not driven by the magnetic instability. These results emphasize a competition between ferromagnetism and antiferromagnetism in these ruthenates with a π^* band $2/3$ filled.

The $n = 2$ members of the RP series, $\text{Ca}_3\text{Ru}_2\text{O}_7$ and $\text{Sr}_3\text{Ru}_2\text{O}_7$, consist of double perovskite layers ‘ $\text{A}_2\text{Ru}_2\text{O}_6$ ’ intergrown with single rock-salt ‘ SrO or CaO ’ layers (Figure 9 (b)). $\text{Ca}_3\text{Ru}_2\text{O}_7$ exhibits, like Ca_2RuO_4 , a metal-to-insulator transition as T decreases, with $T_{\text{MI}} = 48 \text{ K}$ (Cao *et al.*, 2013). Its magnetic phase diagram (Figure 12) shows that it is an antiferromagnetic Mott insulator below 48 K , and becomes a metallic ferromagnet between $T_{\text{MI}} = 48 \text{ K}$ and $T_c = 56 \text{ K}$. Above T_c , this phase becomes paramagnetic and remains metallic. Remarkably, the antiferromagnetic phase becomes metallic as a magnetic field is increased beyond 6 T , suggesting that the system becomes a ferromagnetic metal (FMM). Note that the confluence of the limits at $T = 48 \text{ K}$ and $H = 4.1 \text{ T}$ lead to a multicritical point. Similar to $\text{Ca}_{2-x}\text{La}_x\text{RuO}_4$, the doping of $\text{Ca}_3\text{Ru}_2\text{O}_7$ at Ca sites changes the magnetism and transport properties of this oxide at low concentration. The resistivity decreases as x increases up to 0.04 in $\text{Ca}_{3-x}\text{La}_x\text{Ru}_2\text{O}_7$ (Figure 13): finally, a metallic state to lowest temperatures is obtained for $x = 0.05$. In contrast to $\text{Ca}_{2-x}\text{La}_x\text{RuO}_4$, no ferromagnetism is induced by doping; the antiferromagnetic metallic state characteristic of $\text{Ca}_3\text{Ru}_2\text{O}_7$ persists in zero applied magnetic-field. However, the application of even

Figure 9 Structure of the RP ruthenates $A_{n+1}Ru_nO_{3n+1}$: (a) $n = 1$ A_2RuO_4 , (b) $n = 2$ $\text{A}_3\text{Ru}_2\text{O}_7$, and (c) $n = 3$ $\text{A}_4\text{Ru}_3\text{O}_{10}$.

Figure 10 (a) Evolution of the resistivity and (b) of the magnetization vs. temperature for the oxides $\text{Ca}_{2-x}\text{La}_x\text{RuO}_4$. Reprinted with permission from Cao, G., McCall, S., Dobrosavljevic, V., *et al.*, 2000. Physical Review B 61, R5053–R5057. © American Physical Society.

a modest magnetic field induces a substantial ferromagnetism. The $M(H)$ curves (Figure 14) show that the saturation magnetization M_{sat} decreases sharply as x increases and disappears for $x = 0.04$, demonstrating that the metamagnetic transition is associated with the insulator-to-metal transition. La-doped or not, $\text{Ca}_3\text{Ru}_2\text{O}_7$ exhibits a negative magnetoresistance that can reach as high as 88%, depending on the temperature and magnetic field.

In contrast to $\text{Ca}_3\text{Ru}_2\text{O}_7$, $\text{Sr}_3\text{Ru}_2\text{O}_7$ is an itinerant-electron ferromagnet at low temperature. Single crystals of this compound have been grown. The zero-field-cooled (ZFC) and field-cooled (FC) $M(T)$ curves (Figure 15) of this oxide registered at low field show a large magnetic anisotropy below $T_c = 104$ K, the easy axis being near $[0\ 0\ 1]$. $\text{Sr}_3\text{Ru}_2\text{O}_7$ also shows a broad maximum below T_c with $H \perp (001)$ (inset Figure 15), suggesting the presence of a noncollinear spin structure in the ferromagnetic matrix. The $M(H)$ curves for $H \perp (001)$ in the low-temperature ranges show that the spin system undergoes a transition to a parallel spin configuration for a critical value of the magnetic field smaller than 3 T. This reorientation transition disappears at about 66 K in agreement with an additional transition observed at $T^* = 66$ K in the $M(T)$ curve (Figure 15). All these observations can be explained by a canting of the spins away from the $[0\ 0\ 1]$ directions for $T < T^*$. The resistivity also exhibits a very large anisotropy as shown from the $\rho(T)$ curves (Figure 16); ρ_c/ρ_{ab} is indeed close to 3 at room temperature in accordance with the two-dimensional character of the structure, which favors the delocalization of the carriers within the basal plane of the $\text{RuO}_{6/2}$ octahedra. Note that besides the anomalies at T^* and T_c on the $\rho(T)$ curve, there exists a third anomaly at ~ 250 K whose origin is unknown. Like SrRuO_3 , this oxide

Figure 11 Phase diagram of $\text{Ca}_{2-x}\text{Sr}_x\text{RuO}_4$. Reprinted with permission from Friedt, O., Braden, M., André, G., *et al.*, 2001. Physical Review B 63, 174432. © American Physical Society.

Figure 12 Magnetic phase diagram of $\text{Ca}_3\text{Ru}_2\text{O}_7$. Reprinted with permission from Cao, G., McCall, S., Crow, J.E., Guertin, R.P., 1997. Physical Review Letters 78, 1751–1754. © American Physical Society.

exhibits a negative magnetoresistance, as shown from the $MR(T)$ curve (Figure 17) with $MR = (\rho(0\text{ T}) - \rho(10\text{ T})) / \rho(0\text{ T})$. A peak of magnetoresistance of $\sim 15\%$ observed below T^* suggests that the effect originates mainly from the spin reorientation under the magnetic field. In contrast, the effect at T_c is small compared to SrRuO_3 , which exhibits a maximum MR of $\sim 10\%$ at T_c .

The solid solution of $(\text{Sr}_{1-x}\text{Ca}_x)_3\text{Ru}_2\text{O}_7$ shows continuous changes of lattice parameters and a phase transition from $Bbcb$ to $Bb2_1m$ at $x=0.4$. While the octahedral-site tilting in the basal plane increases with increasing x , the tilting seen in the ac plane onsets at $x=0.4$ corresponding to the structural transition (Peng *et al.*, 2010). As shown in the resistivity $\rho(T)$ (Figure 18), transitions at T_N and T_{MI} remain for $x > 0.4$; but they become much broader. The γ_e in the insulator phase of $x > 0.4$ is small relative to that of the metallic phase of $x=1$. A much enhanced γ_e for the phase $0 < x < 0.4$ indicates strong quantum critical fluctuations below T_f in the regimes III and IV of the phase diagram (Figure 19).

The third member of the RP series, $\text{Sr}_4\text{Ru}_3\text{O}_{10}$ consists of triple perovskite layers 'Ru₃O₉' intergrown with single rock-salt 'SrO' layers. The single-crystal study of this compound shows that, like $\text{Sr}_3\text{Ru}_2\text{O}_7$, this oxide is ferromagnetic with a T_c of 148 K, intermediate between that of SrRuO_3 and $\text{Sr}_3\text{Ru}_2\text{O}_7$. The $M(T)$ curves (Figure 20(a)) show that, in contrast to $\text{Sr}_3\text{Ru}_2\text{O}_7$, the easy axis lies in the ab plane. Also different from the latter phase, there is no clear evidence for spin reorientation at low temperature. The

Figure 14 Magnetization vs. field at 5 K for $(\text{Ca}_{1-x}\text{La}_x)_3\text{Ru}_2\text{O}_7$. Reprinted with permission from Cao, G., Abboud, K., McCall, S., Crow, J.E., Guertin, R.P., 2000. *Physical Review B* 62, 998–1003. © American Physical Society.

saturation value of the magnetization, $1.75 \mu_B$ per formula unit, is in agreement with the low-spin configuration generally observed for $\text{Ru(IV)} d^4$. The $\rho(T)$ curve (Figure 20(b)) of this phase is similar to that observed for SrRuO_3 with a Fisher–Langer anomaly at $T_c = 148$ K. As in SrRuO_3 , a small magnetoresistance is maximum at T_c ($\sim 6\%$ under 10 T) along with the disappearance of the Fisher–Langer anomaly under a magnetic field.

It is significant that in the Sr-RP series, the ferromagnetic T_c increases as the thickness n of the perovskite layers increase whereas in the Ca-RP series, the long-range magnetic-ordering temperature decreases with n , which is consistent with the observation that in the perovskites ($n = \infty$), SrRuO_3 is ferromagnetic and CaRuO_3 undergoes no long-range magnetic order to the lowest temperature.

Ruthenate Hexagonal Perovskite Polytypes

Where large A cations make the perovskite tolerance factor $t > 1$, the cubic structure becomes unstable relative to a hexagonal polytype. In the cubic structure, the (111) AO_3 planes are cubically stacked; in the polytype, some hexagonal stacking of these planes are introduced periodically. Hexagonal stacking creates face-sharing octahedral sites as illustrated in **Figure 21**. Three polytypes of BaRuO_3 are known, 9 R, 4 H, and 6 H; the number refers to the number of AO_3 planes characterizing the c -axis periodicity of the

rhombohedral (R) or hexagonal (H) structure. Prepared under atmosphere pressure, BaRuO_3 has the 9 R structure of Figure 21(b). Prepared under successively higher pressure, the ratio of hexagonally stacked to cubically stacked AO_3 layers decreases from 2:1 in the 9 R phase to 1:1 in the 4 H (Figure 21(a)) to 1:2 in the 6 H (Figure 21(c)), and finally to the 3 C all-cubic stacking of the perovskite phase. All these structures remain stable at low temperatures if the pressure of synthesis is removed at room temperature. The polytypes are a compromise between all hexagonal and all cubic AO_3 -plane stacking, the hexagonal stacking allowing an increased volume for A cations, but at the expense of a large coulomb repulsion across a shared face. Hexagonal stacking introduces a strong axial field that orders the t orbitals of the $t^4e^0\text{Ru}^{\text{IV}}$ configuration into a half-filled xy orbital and $3/4$ -filled $yz \pm izx$ orbitals. As a result, the orbital angular momentum of the Ru^{IV} ions is maximized. Both the 9 R and 4 H phases of BaRuO_3 exhibit an almost temperature-independent paramagnetic susceptibility, signaling Pauli paramagnetism with no detectable local magnetic moment on the $\text{Ru}(\text{IV})$. The 4 H BaRuO_3 phase indeed exhibits a metallic-like resistivity in the range $4 \leq T \leq 300$ K (Figure 22). The 9 R BaRuO_3 phase, on the other hand, shows a metallic-like resistivity only above ~ 100 K; but an up-turn in the resistivity is found below ~ 100 K (Figure 22). Moreover, the resistivity of these materials is sensitive to annealing under different temperatures. The paramagnetic susceptibility of the 9 R phase does not follow the Curie–Weiss law due to strong spin–orbit coupling. The structural change from 9 R to 6 H and to 3 C (perovskite) leads to an evolution of $\chi(T)$ from a non-Curie–Weiss behavior in the 9 R phase to a typical Curie–Weiss behavior and ferromagnetism as illustrated in Figure 23.

The ruthenates $\text{Ba}_3\text{MRu}_2\text{O}_9$, with $M = \text{Fe}, \text{Co}, \text{Ni}, \text{Cu}, \text{In}$, all exhibit a 6 H structure built up of units of two-face shared octahedra occupied by Ru interconnected by single $\text{MO}_{6/2}$ octahedra (Figure 21(c)). In these phases, ruthenium is either pentavalent or mixed valent $\text{Ru}(\text{IV})$ – $\text{Ru}(\text{V})$. In contrast to BaRuO_3 , all these oxides are semiconductors as a result of the Ru dimers separated by the M atoms. Magnetic susceptibility measurements show that the $M-3d$ species have local moments below 400 K and that compounds with $M = \text{Co}, \text{Ni}, \text{Cu}$ exhibit a magnetic transition near 100 K. The magnetic structure of these oxides varies with the nature of the M element. The oxides $\text{Ba}_3\text{MRu}_3\text{O}_9$ with $M = \text{Mg}, \text{Ca}, \text{Cd}, \text{Sr}$ also exhibit the same 6 H structure with a similar ordering of the ruthenium ions into face-shared bi-octahedra and of the M cations in the isolated corner-shared octahedra. These oxides are also semiconductors. The magnetic susceptibility behavior suggests that the d-electrons of the $\text{Ru}(\text{V})$ are delocalized between the two sites of the paired octahedra in agreement with the Heisenberg–Dirac–Van Vleck model.

Pyrochlore Ruthenates

The cubic $\text{A}_2\text{B}_2\text{O}_{7-x}$ pyrochlore structure (Figure 24) also has a B_2O_6 framework of corner-shared $\text{BO}_{6/2}$ octahedra; but this framework is penetrated by an A_2O_{1-x} sublattice in which x may be as high as $x = 1$, but normally is $x = 0$. Ruthenates with the pyrochlore structure have been extensively studied, mainly for their transport properties, which are closely related to their oxygen nonstoichiometry. For instance, $\text{Bi}_2\text{Ru}_2\text{O}_7$ and $\text{Pb}_2\text{Ru}_2\text{O}_{6.5}$ were found to exhibit a metal-like behavior with a resistivity of $\sim 10^{-3} \Omega \text{ cm}$ at room temperature and a Pauli paramagnetism. The nearly temperature-independent resistivity in the vicinity of room temperature has been exploited. Based on XPS, UPS, and EELS studies, it has been shown that the 6 p states of Bi and Pb hybridized with the Ru:4d states via shared O:2 p states. In contrast, rare-earth ruthenates $\text{Ln}_2\text{Ru}_2\text{O}_7$, $\text{Ln} = \text{Pr-Lu, Y}$, were found to be semiconductors with low activation energies. On the other hand, the difference in conductivity between $\text{Ln}_2\text{Ru}_2\text{O}_7$ and $\text{Bi}_2\text{Ru}_2\text{O}_7$ has been attributed to different bending of the Ru–O–Ru bond, which is 128° in $\text{Ln}_2\text{Ru}_2\text{O}_7$ and 138° in $\text{Bi}_2\text{Ru}_2\text{O}_7$. This viewpoint is supported by a study of the solid solution $\text{La}_{2-x}\text{Cd}_x\text{Ru}_2\text{O}_7$, which also exhibits metallic conductivity and has Ru–O–Ru bond angles similar to that of $\text{Bi}_2\text{Ru}_2\text{O}_7$, but is characterized by large paramagnetic susceptibilities. Similarly, the studies of the solid solutions $\text{Bi}_{2-x}\text{Ln}_x\text{Ru}_2\text{O}_7$ and $\text{Pb}_{2-x}\text{Ln}_x\text{Ru}_2\text{O}_7$ with $\text{Ln} = \text{Y, Pr-Lu}$, clearly show that the metal–insulator crossover

Figure 21 Structures of (a) 4H BaRuO₃, (b) 9R BaRuO₃, and (c) 6H Ba₃MRu₂O₉ where blue circles represent Ru and red circles M elements.

Figure 22 Resistivity vs. temperature for 4H and 9R BaRuO₃ forms. Reprinted with permission from Rijssenbeek, J.T., Jin, R., Zadorozhny, Yu, *et al.*, 1999. observed for these oxides at temperatures ranging from 40 to 80 K is correlated to the bending of the Ru–O–Ru bond and to the distortion of the RuO₆ octahedra. Finally, the pyrochlore $\text{Ti}_{2-x}\text{Ru}_x\text{O}_{7-\delta}$, which was synthesized under high pressure, is a good example of the great influence of cationic and oxygen nonstoichiometry upon the transport properties of this structural family. Under reducing conditions, these phases exhibit a metallic behavior (**Figure 25(a)**) whereas in neutral atmosphere (**Figure 25(b)**) or under high oxygen pressure (**Figure 25(c)**), they show a metal-to-insulator transition at about 40 and 120 K, respectively. The latter transitions are correlated to structural changes versus temperature. The magnetic properties of these oxides are so far not completely characterized; their spin-glass behavior and magnetic anomalies at different temperatures (40 and 120 K) depends on

Figure 23 Inverse magnetic susceptibility vs. temperature of BaRuO₃. After Jin, C.-Q., Zhou, J.-S., Goodenough, J.B., *et al.*, 2008. Proceedings of National Academy of Sciences USA 105, 7115–7119.

Figure 24 Pyrochlore structure of A₂Ru₂O_{7-δ} ruthenates.

the conditions of synthesis, i.e., their oxygen content. A neutron powder diffraction study revealed in great detail the structural change on crossing the metal–insulator transition. On cooling through T_{MI} , the Ru–O bond length in the Ru₁ array shrinks sharply whereas that in the Ru₂ array expands (Figure 26). A DFT calculation indicates an orbital ordering in the insulator phase, which leads to the formation of quasi-1D chains.

The Quasi-Two-Dimensional Ruthenates

The ruthenate SrRu₂O₆ with the defect 3D KSbO₃ structure can be made if the synthesis is performed in a sealed Au tube at 700 °C and 3000 atm pressure. The low-temperature hydrothermal synthesis can lead to a 2D PbSb₂O₆-type structure (Figure 27) with $a = 5.20573$ Å and $c = 10.46908$ Å in the space group $P-31c$. Spins on Ru(V) are coupled antiferromagnetically within the RuO₆ octahedra layers with a $T_N \approx 560$ K. A similar layered honeycomb structure with the $C2/m$ space group has been found in Li₂RuO₃ ($a = 5.021$ Å, $b = 8.755$ Å) and Na₂RuO₃ ($a = 5.346$ Å, $b = 9.255$ Å). In sharp contrast to Ru(V) in SrRu₂O₆, the spins on Ru(IV) are ordered antiferromagnetically at 9 K in Li₂RuO₃ and 30 K in Na₂RuO₃ (Wang *et al.*, 2014).

Figure 27 Crystal structure of SrRu_2O_6 ; dark grey balls, Sr; red balls, oxygen; Ru, inside octahedra.

The Quasi-One-Dimensional Ruthenates Ln_3RuO_7

The lanthanide ruthenates Ln_3RuO_7 ($\text{Ln} = \text{La-Sm}$) exhibit, from the viewpoint of the Ru arrangement, a 1D-type structure built up of chains of corner-sharing RuO_6 octahedra. The magnetic and transport properties of La_3RuO_7 reflect its 1D geometry. This phase is a semiconductor even along the chain, though the Ru–O–Ru angles of 145° are very similar to those observed for 3D pyrochlore ruthenates. The magnetic data show that this Ru(V) oxide exhibits a Curie–Weiss behavior above 50 K and an antiferromagnetic order below this temperature. In fact, a short-range antiferromagnetic order is observed in the range 20–50 K which becomes long range below 20 K.

Ruthenium as a Substituting Element in Oxides

The ability of ruthenium to adopt an octahedral coordination makes it possible to substitute it for transition elements in many oxides. As a consequence, its electronic configuration either as Ru(IV) or as Ru(V) and the large extension of its d orbitals, suggests that such an element is susceptible to induce new physical properties in already known materials. Two examples of this promising role of Ru to induce new properties are described.

The first example deals with the introduction of Ru into the 1212 structure of cuprates. It has been discovered that the ruthenium-doped 1212 cuprate $\text{RuSr}_2\text{GdCu}_2\text{O}_8$ is both a superconductor with a $T_c = 15\text{--}40\text{ K}$, and a ferromagnet with a $T_c = 133\text{--}136\text{ K}$ (Figure 28). The coexistence of superconductivity and ferromagnetism below 15–40 K appears most surprising since,

Figure 28 AC susceptibility measurements of $\text{RuSr}_2\text{Cu}_2\text{O}_8$, showing that superconductivity exists up to 35 K, with a superconductive $T_c = 18\text{ K}$ and a Curie temperature $T_c = 133\text{ K}$. Figure 29 The 1212 structure of $\text{RuSr}_2\text{GdCu}_2\text{O}_8$ built up of layers of RuO_6 octahedra stacked with layers of CuO_5 pyramids.

according to Ginzburg, such a feature should not be possible at a microscopic scale. The particular layered structure of this compound (**Figure 29**), which consists of superconducting pyramidal copper layers stacked with octahedral ruthenium layers, is certainly the key to understanding this behavior since this structural separation should decrease the interactions between ferromagnetism and superconductivity dramatically. In any case, this extraordinary behavior has prompted numerous investigations still in progress to help understand the physics of these materials.

The second example deals with the doping of perovskite manganites with ruthenium. It has been shown that the partial substitution of ruthenium for manganese in charge-ordered manganites such as $\text{Sm}_{0.5}\text{Ca}_{0.5}\text{MnO}_3$, which are insulator ferromagnets, induces ferromagnetism and a metal–insulator transition with consequently, colossal magnetoresistance (CMR) effects. Thus, a very high T_c up to 220 K can be reached by Mn-site doping, changing completely the magnetic-phase diagram of the manganites. This situation is illustrated for $\text{Sm}_{1-x}\text{Ca}_x\text{MnO}_3$ (**Figure 30(a)**) doped with 12% Ru (**Figure 30(b)**). It can be seen that the T_c of the ferromagnetic insulating region is increased by Ru substitution; but more importantly, the broad charge-ordered antiferromagnetic domain (**Figure 30(a)**) is suppressed and replaced by a ferromagnetic metallic region with a T_c up to 200 K. This great ability of Ru to induce ferromagnetism and metal-like behavior can be explained by both its ability to couple ferromagnetically with manganese neighbors and the large extension of its d-orbitals allowing stronger interatomic interactions and, therefore, conduction paths to be enhanced.

Figure 30 Magnetic phase diagrams of the manganites $\text{Sm}_{1-x}\text{Ca}_x\text{MnO}_3$ (a) and $\text{Sm}_{1-x}\text{Ca}_x\text{Mn}_{0.88}\text{Ru}_{0.12}\text{MnO}_3$ (b).

Introduction

Immediately after the laser invention it was realized that laser beams, with a carrier frequency of some 10^{14} Hz, have the potential to transport information with a much larger frequency band than either radio or microwaves. Atmospheric transmission is limited to line-of-sight communications and is strongly dependent on visibility conditions. It was therefore natural to think about a waveguide having the function of creating a protected path for the light beam, and also of compensating diffraction by optical confinement. Indeed, an optical wave having a finite transversal size broadens during propagation in free space. If we consider the output of a typical laser working at the wavelength λ , this is represented by a Gaussian wave with a beam diameter d of the order of 1 mm. The diffraction angle θ (also called the divergence of the beam) is of the order of λ/d . Taking $\lambda = 1 \mu\text{m}$, we find that at the distance $L = 1 \text{ km}$ the beam diameter becomes 1 m. At present, guided-wave optics is an important technology with applications that are not limited to the transmission of optical signals, but also involve the fabrication of integrated optical and optoelectronic devices, such as lasers and modulators. The basic concept of optical confinement is simple. A dielectric medium of refractive index n_1 , embedded in a medium of lower refractive index n_2 , acts as a light trap within which optical rays remain confined by multiple internal reflections at the boundaries. The optical waveguide may have the shape of a slab, strip, or cylinder. The most widely used is the optical fiber, which is made of two concentric cylinders of glass or polymeric material. Silica glass fibers represent by far the most important family of fibers, because they can transmit optical pulses over long distances with small attenuation and limited pulse broadening. The fibers made of polymeric material, called plastic optical fibers (POF), although presenting much larger losses than silica fibers, have the advantage of a much cheaper fabrication process, and can be competitive for the short links required in a variety of applications, including communication networks inside a building or a vehicle.

Besides telecommunications, important applications of optical fibers are found in the areas of sensing and of biomedical imaging. Fiber sensors can measure temperature, pressure, strain, current flow along high-voltage power lines, and rotations in aircraft navigation. Fiber-optic endoscopy utilizes fiber bundles to guide light into the internal area under investigation and to transmit back the image.

Structure and Modes

The structure of an optical fiber is shown in **Figure 1**. Typically, the cladding is made of pure silica, whereas the core is doped with germania during manufacturing in order to increase its refractive index and introduce a positive index step between core and cladding. In many cases, instead of having a step in the refractive index profile, the refractive index of the core is graded from a maximum value at its center to a minimum value, corresponding to the refractive index of the cladding, at the core-cladding boundary. The fiber is then called a graded-index fiber, whereas the fiber shown in **Figure 1** is called a step-index fiber. For optical-communication fibers, the cladding diameter is typically $125 \mu\text{m}$, and the core diameter can vary from 9 to $50 \mu\text{m}$ depending on the application.

An elementary description of light trapping in the core of a step-index fiber can be based on total internal reflection: since $n_1 > n_2$, when the angle of incidence β on the core-cladding interface is larger than the limit angle $\beta_c = \arcsin(n_2/n_1)$, total internal reflection occurs, so that the beam can propagate for an indefinite distance within the fiber core without radiating outside any

[☆]*Change History:* June 2015. V. Degiorgio and I. Cristiani introduced small edits in the text of the article including a sentence about the fiber Raman laser and updated citations.

Figure 1 (a) Scheme of an optical fiber. (b) Waveguiding effect by total internal reflection.

optical power. If we consider an optical ray whose propagation direction forms an angle α with the axis of the fiber, it is easy to derive that the maximum acceptance angle, $\alpha_{\max}$, is given by:

$$\sin \alpha_{\max} = n_1 \sqrt{1 - \sin^2 \beta_c} = \sqrt{n_1^2 - n_2^2} \quad [1]$$

The quantity $\sin \alpha_{\max}$ is called numerical aperture of the fiber, and is indicated with the symbol NA . Considering a realistic case in which $n_1 = 1.48$, $n_2 = 1.46$, we find that the numerical aperture is 0.24, and $\alpha_{\max} = 14^\circ$.

The geometrical picture of light guidance by multiple reflections is not adequate to explain the propagation properties of the fiber. In particular, geometrical optics suggests a complete confinement of the light beam within the core, whereas wave optics predicts a non-zero intensity in the cladding region (evanescent wave). The general treatment requires solving the wave equation with the appropriate boundary conditions. Since it goes beyond the scope of this article to discuss such a treatment, we limit ourselves to a description of the main results. Assuming that the electromagnetic wave is monochromatic (that is, it contains a single frequency ν) and that nonlinear optical effects are negligible, it is found that there is a set of field configurations, called fiber modes, which can propagate without attenuation maintaining the same transversal distribution and the same polarization at all distances along the waveguide axis. In most practical cases the full set of modes can be approximated by a set of so-called 'linearly polarized' LP_{mn} modes, where the indices m and n are integer numbers. An LP_{mn} mode has n field maxima along a radius vector and $2m$ field maxima round a circumference. By calling E_{mn} the electric field associated to the mode mn , and choosing the z -axis coincident with the fiber axis, the fiber mode is characterized by a transversal field distribution $A_{mn}(x, y)$ and by a propagation constant β_{mn} , both depending on m and n :

$$E_{mn}(x, y, z, t) = A_{mn}(x, y) e^{i(\beta_{mn}z - \omega t)} \quad [2]$$

where $\omega = 2\pi\nu$ is the angular frequency. We show in **Figure 2** the amplitude profile of the fundamental mode LP_{01} that is approximately described by a Gaussian function:

$$A_{01}(r) = A_0 \exp\left(-\frac{r^2}{w^2}\right) \quad [3]$$

where $r = (x^2 + y^2)^{1/2}$ is the distance from the fiber axis. We see that the field amplitude $A_{01}(x, y)$ is mainly concentrated inside the core, but presents exponentially decaying tails extending into the cladding region. Higher-order modes present more complicated profiles extending more and more deeply into the cladding as the indices m and n become larger and larger.

Figure 2 Field profile of the fundamental propagation mode LP_{01} for various values of the normalized frequency V .

In order to discuss fiber properties it is helpful to introduce the dimensionless parameter V , called normalized frequency, defined as:

$$V = \frac{2\pi a}{\lambda} \sqrt{n_1^2 - n_2^2} \quad [4]$$

where $\lambda = c/v$ is the wavelength. The plots in [Figure 2](#) indicate that the beam size w is a decreasing function of V . This can be easily understood if we note that the beam is more tightly confined when the core size is large in comparison with the wavelength, and when the difference in refractive index between core and cladding is large.

From the propagation constant β_{mn} one can derive the effective index of refraction n_{mn} seen by the mode mn , by using the relation: $\beta_{mn} = 2\pi n_{mn}/\lambda$. The value of n_{mn} will be clearly intermediate between n_1 and n_2 , approaching more closely n_1 when the field mode is more tightly confined.

A very important general property of waveguides is that, for a fixed waveguide configuration and a fixed λ , a fundamental mode always exists, whereas higher-order modes can be sustained only under specific conditions. In the case of optical fibers the parameter controlling the single-mode or multimode behavior is the normalized frequency V . If V is sufficiently small, the fiber is single-mode. When V becomes larger than a critical value V_c , also the second mode can be sustained. By progressively increasing V , more and more modes can be guided. For $V \gg 1$, the number N of guided modes is given by: $N \cong V^2/2$.

The value of V_c is dependent on the fiber structure. In the case of the step-index fiber, $V_c = 2.405$. Fibers that are single-mode at $\lambda = 1500$ nm are usually designed with values of V close to 2, by choosing a core radius around $5 \mu\text{m}$ and a difference $n_1 - n_2$ around 10^{-2} . Note that, since V is inversely proportional to λ , a fiber that is single-mode in the near infrared will be multi-mode in the visible.

Multi-mode fibers have typically a core diameter around $50 \mu\text{m}$. They are easier to align and less expensive than single-mode ones. However, as discussed below in the Section dealing with dispersion, they are not fit for pulse transmission over long distances because pulse-broadening effects are large.

Attenuation

In principle a guided mode can propagate in an optical fiber for arbitrary distances without suffering radiation losses. In practice, however, the propagating wave is always attenuated. Assuming that the losses are linear, the optical power P_o launched into the fiber decays exponentially along the fiber following the law:

$$P(z) = P_o e^{-\alpha_o z} \quad [5]$$

where α_o , expressed in km^{-1} , is the attenuation coefficient. In practice, the quantity given in fiber specifications is the coefficient $\alpha = 4.34 \alpha_o$ expressing the attenuation in dB km^{-1} .

The attenuation is due to two phenomena: light scattering and absorption. Light scattering is originated by the microscopic inhomogeneities that exist in the glass at the drawing temperature because of spontaneous thermal fluctuations. Such inhomogeneities are frozen during the rapid cooling process, and give rise to spatial fluctuations of the refractive index over a sub-micrometric scale. Rayleigh scattering from these fluctuations has a cross-section that scales according to λ^{-4} . As a consequence, scattering losses rapidly decrease as a function of wavelength.

Optical fibers are usually made of fused silica glass (SiO_2). This material has two strong absorption bands, a ultraviolet band around $0.3 \mu\text{m}$ due to electronic transitions and an infrared band around $1.7 \mu\text{m}$ due to the vibrational mode of the Si-O bond. The presence of water impurities gives other absorption peaks due to vibrations of the OH^- ion, the most important one near 1370 nm. Because of the combined effect of scattering and absorption, the attenuation curve for silica glass, as shown in [Figure 3](#), has an absolute minimum at 1550 nm and a secondary minimum around 1300 nm. The OH^- absorption peak no longer exists in recent fibers, because of improvements in the purification process. However, several networks using fibers with water impurities are still installed and in use.

The earliest optical communication schemes were working at about 800 nm, where the attenuation has a local minimum, not apparent in [Figure 3](#). The value of the attenuation at the absolute minimum, $\alpha_{\min}$, is about 0.15 dB km^{-1} , corresponding to a reduction of the input power by a factor of two after a propagation length of 20 km. Optical communication systems operate around the wavelength corresponding to the minimum attenuation.

If different oxides are added to SiO_2 , the position of $\alpha_{\min}$ is only slightly changed because essentially all oxides present vibrational transitions in the range $1.5\text{--}2 \mu\text{m}$. A significant shift of the minimum attenuation can be obtained by using glasses made with mixtures of fluorides, such as the so-called ZBLAN glasses that contain Zr, Ba, La, Al, and Na fluorides. Since vibrational levels of fluorides are localized in the range $5\text{--}8 \mu\text{m}$, ZBLAN glasses present the attenuation minimum around $3 \mu\text{m}$, with a value of $\alpha_{\min}$ one order of magnitude smaller than that of silica glasses. It is, however, rather difficult to draw ZBLAN fibers of good optical quality.

It should be mentioned that fiber losses increase considerably if the fiber is curved. This can be easily understood in the frame of geometrical optics: if the fiber is curved, there is a change of the incidence angle at the core-cladding interface and some rays may be

Figure 3 Dependence of the attenuation coefficient α of silica glass on the wavelength λ .

not totally reflected. Such a radiation loss affects in particular the modes presenting a field distribution that extends considerably into the cladding, as it happens when the normalized frequency V is small.

Dispersion

In Optics the term dispersion indicates that the index of refraction of the medium changes with the frequency of the propagating wave, $n = n(\omega)$. An optical pulse with duration Δt has a spectral broadening $\Delta\omega \geq \Delta t^{-1}$, and cannot be treated as a monochromatic wave. Each frequency component travels in the dispersive medium with a different phase velocity $v_\phi = c/n(\omega)$. As a consequence, the pulse shape changes during propagation. If we assume that the input pulse is transform-limited, which means that all the frequency components have the same phase, the effect of dispersion is a progressive increase of the pulse duration as the propagation length increases.

If the wave, instead of propagating in a homogeneous medium, propagates along an optical fiber, its velocity is determined by the effective index of refraction n_{mn} defined above. Note that, even in absence of material dispersion, the effective index of refraction changes with frequency because the mode profile is frequency-dependent. Therefore the fiber is dispersive even in absence of dispersion of the materials constituting the fiber. This results in a waveguide contribution that must be added to the material contribution to obtain the total fiber dispersion.

Laser pulses have a spectral broadening $\Delta\omega$ usually much smaller than the central frequency ω_o . This allows treating the wave propagation in a dispersive medium by using a perturbative approach. The propagation constant $\beta(\omega)$ is expanded in a power series around ω_o , and the series is truncated to the quadratic term:

$$\beta(\omega) = \beta_o + \beta_1(\omega - \omega_o) + \frac{1}{2}\beta_2(\omega - \omega_o)^2 \quad [6]$$

where β_j is the j -th derivative of $\beta(\omega)$ evaluated at $\omega = \omega_o$. By using eqn [6] inside the propagation equation, it can be shown that the reciprocal of β_1 is the group velocity (that is, the velocity of the pulse peak) and that β_2 is the parameter responsible for pulse broadening, usually called group velocity dispersion (GVD). If we assume that the input pulse is a transform-limited Gaussian pulse having duration equal to Δt_o , the pulse duration Δt after a path-length z is given by:

$$\Delta t = \sqrt{(\Delta t_o)^2 + \left(\frac{|\beta_2|z}{\Delta t_o}\right)^2} = \Delta t_o \sqrt{1 + \left(\frac{z}{L_D}\right)^2} \quad [7]$$

where $L_D = (\Delta t_o)^2 / |\beta_2|$ is called the dispersion length. Equation 7 indicates that dispersion effects become more and more important as the pulse duration becomes shorter and shorter. Considering, for instance, a standard single-mode optical-communication fiber at 1550 nm, $\beta_2 = -20 \text{ ps}^2 \text{ km}^{-1}$, and $\Delta t_o = 10 \text{ ps}$, we find $L_D = 5 \text{ km}$. This means that the pulse duration is more than doubled when $z = 10 \text{ km}$. Clearly, pulse broadening can be very detrimental in long communication links because it produces a smearing out of individual bits, leading to higher bit error rates. In order to reduce such an effect, fibers with low value of β_2 around 1550 nm have to be used. These special fibers, called dispersion-shifted fibers, are fabricated by an appropriate choice of refractive-index profile. We show in Figure 4 the behavior of β_2 as a function of λ for a standard single-mode fiber and for a dispersion-shifted fiber.

Multi-mode fibers present an additional dispersion mechanism due to the fact that different modes, even if operating at the same wavelength, have different field profiles, hence different effective refractive indices. Therefore, if the pulse input power is coupled

Figure 4 The dispersion parameter β_2 plotted as a function of wavelength for a standard single-mode fiber, a dispersion-shifted fiber, and a microstructured fiber.

simultaneously to several modes, modal dispersion gives a contribution to pulse broadening that can be larger than that due to material- and waveguide-dispersion.

Special Fibers

Besides step-index and graded-index fibers, other types of fibers having a more complicated index profile are used for special purposes. In the previous Section we have mentioned dispersion-shifted fibers, designed to present a reduced dispersion in a specific wavelength range. Another useful category is that of polarization-maintaining fibers, fibers presenting some anisotropy in the index profile that makes them birefringent. A very recent development consists in fibers presenting air holes running along the fiber axis. An example is shown in [Figure 5](#). These are called micro structured fibers, and may have a variety of applications connected with the fact the air-silica structure allows single-mode behavior over a very wide wavelength range and gives more freedom in choosing the area of the propagating mode or the shape of the dispersion curve.

Figure 5 Cross-section of a microstructured fiber made of silica with air holes running along the fiber axis. The silica core has a diameter of about 2 μm .

Fiber Bragg Gratings

It is very helpful to be able to manipulate optical signals traveling inside fibers without extracting them from the fiber. This not only reduces losses, but also makes the optical system more flexible. Following the all-fiber approach, various optical components and devices have been conceived and built in order to perform a variety of functions, such as beam splitters and combiners, mirrors, filters, polarizers, amplifiers, and even lasers. In this Section we describe frequency-selective mirrors obtained by introducing inside the fiber core a longitudinal modulation of the refractive index with given periodicity. Such a modulation acts as a phase grating, the structure is indeed called 'fiber Bragg grating' (FBG). The behavior can be understood by similarity with a multilayer dielectric mirror: a sequence of weakly reflecting surfaces can become a high reflectivity structure if a constructive interference condition is established among all the reflected fields. Calling Λ the grating period, such a condition requires that the phase shift suffered by the field propagating over the distance Λ be π (or a multiple of π) – the condition is satisfied for the wavelength λ_o given by:

$$\lambda_o = 2n\Lambda \quad [8]$$

where n is the average refractive index of the fiber core. If we call Δn the amplitude of the refractive-index modulation and N the number of grating periods, the peak reflectivity is given by:

$$R_{\max} = \tan^2 \left(N \frac{\Delta n}{n} \right) \quad [9]$$

Typically the grating length L is of the order of millimeters, that is, $N=L/\Lambda$ is in the range $10^3 - 10^4$. Therefore $R_{\max}$ can be close to 100%, even if Δn is small. The bandwidth of the FBG mirror is a decreasing function of N , so that the reflectivity peak can become very narrow for large N .

FBGs are fabricated by exploiting the photosensitivity of the Ge-doped core of silica fibers. The presence of Ge atoms leads to the formation of oxygen-deficient bonds that represent defects in the silica matrix. The energy required to break the bond is about 5 eV. The absorption of a 244-nm photon from an excimer laser can break the defect-bond, resulting in a change of absorption spectrum and in a corresponding change in refractive index. Since index changes occur only in the spatial regions where ultraviolet light is absorbed, by illuminating the fiber core with a periodic intensity pattern an index-of-refraction grating is generated.

Fiber Amplifiers and Lasers

An important family of materials used for optical amplification is represented by dispersions of rare-earth ions, such as neodymium or erbium or ytterbium, in a solid matrix that can consist of a crystal or a glass. An interesting extension of the idea of the rare-earth solid-state optical amplifier is the fiber amplifier, which utilizes silica fibers doped with rare-earth ions. Optical amplification is extremely important in long-distance optical-communication links in order to compensate for fiber attenuation, so that the optical power can be maintained at sufficiently high levels along the path to ensure a satisfactory signal-to-noise ratio. Doped fibers can provide wide-band amplification at wavelengths around 1550 nm, corresponding to the attenuation minimum for silica fibers.

The most important fiber amplifier is based on Erbium-doped silica fibers and uses a transition of the Er^{3+} ion in a wavelength range extending from 1530 to 1560 nm. The energy level diagram of the ion Er^{3+} is shown in Figure 6. The upper level of the 1530-nm transition is metastable (with a lifetime of 12 ms), thus permitting to easily achieve population inversion by exciting the ion with radiation at 980 or 1480 nm. The pump field comes from a semiconductor laser, either GaAlAs (980 nm) or InGaAsP (1480 nm). A scheme of the amplifier configuration is shown in Figure 7. The pump field and the signal field are injected into the single-mode doped fiber by using a dichroic coupler. After the doped fiber an optical isolator is inserted in order to eliminate back-reflections. The length of the amplifying fiber is typically around 10 m, and the optical gain can be as large as 10000. The efficiency

Figure 6 Energy levels of the Er^{3+} ion.

Figure 7 Scheme of an Erbium-doped fiber amplifier, pumped by a semiconductor laser. WDM (Wavelength Division Multiplexer) indicates a wavelength dependent combiner.

of the amplifier is large because the single-mode fiber ensures a very good spatial overlap between pump field and signal field. The conversion efficiency can be further improved by using a mixed erbium–ytterbium doping.

Any optical amplifier can be converted into a laser oscillator if a positive feedback scheme is provided. The fiber amplifier can become a fiber laser by placing the amplifier in between two mirrors, constituted, for instance, by two FBCs. Since the fiber is very thin, the surface to volume ratio is large, thus permitting very efficient heat dissipation without using the water-circulation cooling system typical of power lasers. When using a single-mode fiber, the output beam has a very smooth Gaussian profile, therefore it can be focused to a very small focal spot, at variance with the behavior of high-power semiconductor or Nd-YAG lasers. Fiber lasers can work either continuous or pulsed. Rare-earth-doped fibers with their broad gain bandwidth are convenient laser media for the generation of ultrashort optical pulses.

In order to improve the coupling between the semiconductor pump laser and the amplifier, a new fiber geometry involving a double cladding was introduced. A very successful fiber laser using such geometry is the ytterbium laser, which is pumped around 915 nm and can emit in a wide band centered around 1100 nm. Continuous-wave Yb fiber lasers with an output power as large as 1 kW and efficiency of 75–80% are now available. Because of its efficiency, compactness, and simplicity of cooling requirements, the Yb fiber laser is often used in industrial processes, such as marking, welding, and precision cutting.

Nonlinear Fiber Optics

Nonlinear optical effects are particularly efficient in single-mode optical fibers despite the relatively small third-order susceptibility of silica glass. The reason for this is that the spot size of the propagating beam is small and the interaction length can be very long, due to wave guiding and to low losses. A point of great conceptual relevance is that most of the treatments of nonlinear propagation are developed for plane waves, whereas experiments in bulk materials are performed with laser beams that can be considered as Gaussian waves. Therefore diffraction can play a significant role in the experiments, making the comparison with the plane-wave theory sometime difficult. The nonlinear propagation inside the optical fiber can be treated in most cases by assuming that the transversal field distribution is invariant along the propagation distance, so that the propagation problem becomes spatially unidimensional as in the case of the plane-wave approach. This makes much simpler the comparison between theory and experiment.

The two most important nonlinear phenomena in nonlinear fiber optics are the optical Kerr effect and stimulated Raman scattering (SRS).

The optical Kerr effect, that is, the linear dependence of the index of refraction on the beam intensity, gives rise to a self-induced phase shift experienced by the optical field during its propagation, called self-phase modulation (SPM). SPM is responsible for the spectral broadening of optical pulses. In normal dispersion the consequence is that SPM gives an additional contribution to the spreading out in time of the pulse. There is however an interesting situation, corresponding to positive Kerr effect and negative GVD, in which there is a compensation between the two effects, so that an optical pulse of appropriate intensity and shape (optical soliton) can propagate with constant shape and amplitude over a distance that is limited in practice only by the linear attenuation in the fiber. Indeed, several beautiful experiments showing the onset and development of solitonic propagation have been performed. With standard fibers the wavelength range of negative GVD is above 1.3 μm , but the new fibers presenting an air-silica microstructure (see the Section Special Fibers) can shift to lower wavelengths the negative GVD region, as shown in Figure 4, so that solitonic propagation in the visible can be observed.

Concerning SRS, we recall that, starting from a pump wave at frequency ν_p , the effect of SRS is that of generating a strong signal, called the Stokes wave, at a frequency $\nu_s = \nu_p - \nu_v$, where ν_v is a vibrational frequency typical of the considered medium. In the case of silica fibers, the main effect is associated with vibrations of the Si–O bond, occurring at $\nu_v = 12$ THz. SRS can be used to amplify a weak signal at frequency ν_s in presence of a pump ν_p . Raman amplification is very attractive for applications in optical

communications because, at variance with what happens in erbium-doped fiber amplifiers, it is non-resonant, so that it can be used for any ν_s , provided the appropriate pump is available.

SRS is a very interesting method not only to amplify signals, but also to generate new laser wavelengths by converting the Raman fiber amplifier into an oscillator. The availability of high-power diode lasers as pump sources and the development of high reflectivity FBGs makes it possible the realization of nested cavities in which several Stokes lines can simultaneously resonate. In this configuration the pump power can be very efficiently converted to the highest-order Stokes line.

Introduction

During the past 100 years, light-emitting diodes (LEDs) have undergone a significant evolution. The first LED emitting in the visible wavelength region was based on a SiC compound semiconductor. The device had an external quantum efficiency (EQE) of much less than 1.0%. Today, the external efficiencies of red LEDs based on AlGaInP can exceed 50%; this semiconductor is also capable of emitting in the orange, amber, and yellow wavelength range. AlGaInN compounds can emit efficiently in the near ultraviolet (near UV), violet, blue, cyan, and green wavelength range. Thus, all colors of the visible spectrum are covered by semiconductor materials. This has opened up the use of LEDs in areas as diverse as indicator, signage, display, and lighting applications. In particular, as device output powers continuously increase, LED lamps have reached luminous flux levels of, for example, 800 lm, comparable to those of conventional incandescent and fluorescent lamps. Furthermore, LED lifetimes exceeding 20000 h compare favorably with incandescent sources (~ 500 h) and fluorescent sources (~ 5000 h) thereby contributing to the attractiveness of LEDs.

Inorganic LEDs are generally based on p–n junctions. However, in order to achieve high internal quantum efficiencies, free carriers need to be spatially confined. Furthermore to reduce reabsorption effects, the bandgap energy of the confinement layers should be greater than the bandgap energy of the active region. These requirements led to the development of heterostructure LEDs that employ different semiconductor materials (i.e., alloy compositions) for the light-emitting active region and the confinement regions. Particularly popular are multiple quantum wells (QWs) embedded into the active region. The light-extraction efficiency, which measures the fraction of photons leaving the semiconductor die (and thus become useful, i.e., visible photons), is strongly affected by the device shape and surface structure. For devices with high internal-efficiency, maximizing the light-extraction efficiency is a key challenge.

This article concerns inorganic LEDs and introduces the basic concepts of optical emission. Band diagrams of direct-gap and indirect-gap semiconductors and the spectral shape of spontaneous emission will be discussed along with electrical properties and current flow. Subsequently, strategies to improve light extraction out of the LED chip are presented including surface roughening and chip shaping. Due to total internal reflection at the surfaces of an LED chip, the light-extraction efficiency in standard devices is well below 100%. A particular challenge in achieving efficient emission is the minimization of optical absorption processes inside the semiconductor. This can be achieved by, for example, covering absorbing regions, such as absorbing substrates, with highly reflective mirrors. The development of white LEDs, including phosphor-based approaches and multiple-LED approaches, is presented and their properties, such as color rendering and luminous efficacy, are discussed. A short section will address the accomplishments and challenges in deep ultraviolet (DUV) LEDs. Finally, the current state of the art in LED packaging including packages with low thermal resistance, will be discussed.

Recombination in Direct-Gap and Indirect-Gap Semiconductors

The probability that electrons and holes recombine radiatively is proportional to the product of electron and hole concentration, that is, $R \propto np$. The recombination rate per unit time per unit volume can be written as

$$R = -\frac{dn}{dt} = -\frac{dp}{dt} = Bnp \quad [1]$$

[☆]*Change History:* March 2015. E.F. Schubert, J. Cho, and J.K. Kim completely rewrote the article.

Figure 1 Semiconductor band structure for a (a) direct-gap semiconductor, (b) indirect-gap semiconductor, and (c) indirect-gap semiconductors with a deep isoelectronic impurity level. Indirect radiative transitions have a much smaller probability due to the requirement of a phonon.

where B is a proportionality constant, the bimolecular recombination coefficient, with a typical value of $10^{-10} \text{ cm}^3 \text{ s}^{-1}$ for direct-gap III–V semiconductors. Fundamental types of band structures and associated recombination processes are shown in **Figure 1**.

During the recombination process, the electron momentum ($p = (2m^*E)^{1/2}$) cannot change significantly because momentum must be conserved and the photon momentum ($p = h/\lambda$) is negligibly small. Thus optical transitions must be ‘vertical’ in nature, that is, electrons recombine only with holes that have the same k value as shown in **Figure 1**. Efficient recombination occurs in direct-gap semiconductors shown in **Figure 1(a)**. However, the recombination probability is much lower in indirect-gap semiconductors because a phonon is required to satisfy momentum conservation, as shown in **Figure 1(b)**. The radiative efficiency of indirect-gap semiconductors can be increased by isoelectronic impurities, for example, N in GaP. Isoelectronic impurities can form an optically active deep level that is localized in real space (small dx) but, according to the uncertainty relation, delocalized in k space (large dk), so that the impurity can satisfy the momentum conservation, as indicated in **Figure 1(c)**. During nonradiative recombination, the electron energy is converted to vibrational energy of lattice atoms, that is, phonons. There are several physical mechanisms by which nonradiative recombination can occur with the most common ones being nonradiative recombination at point defects (impurities, vacancies, interstitials, anti-site defects, and impurity complexes) and spatially extended defects (screw and edge dislocations, cluster defects, and surfaces of structural cracks). It is quite common for such defects to form one or several energy levels within the forbidden gap. The defects act as efficient recombination centers (Shockley–Read–Hall or SRH recombination centers), particularly if the center’s energy level is close to the middle of the gap.

Optical Emission Spectrum

The spectral line-width of spontaneous emission can be calculated to be $1.8 kT$ (see, e.g., Schubert, 2006). The theoretical emission spectrum is shown in **Figure 2**. The line-width of $1.8 kT$ is caused by the thermal energy of carriers and is therefore referred to as the ‘thermal broadening.’ It indicates that the line-width broadens with increasing temperature. It also indicates that the line-width becomes narrower at cryogenic temperatures. For example, at room temperature, the theoretical line-width of a GaAs LED emitting at 870 nm is $\Delta E = 46 \text{ meV}$ or $\Delta\lambda = 28 \text{ nm}$.

The spectral line-width of LED emission is important in several respects. *Firstly*, the line-width of an LED emitting in the visible range is relatively narrow compared with the range of the entire visible spectrum. Furthermore, the LED emission is narrower than the spectral width of a single color as perceived by the human eye. For example, *red* colors range from 625 to 770 nm ($\Delta\lambda = 105 \text{ nm}$), which is much wider than the typical emission spectrum of a red LED ($\Delta\lambda \approx 25 \text{ nm}$). Therefore, LED emission is perceived (by the human eye) as *monochromatic*. *Secondly*, optical fibers are dispersive, which leads to a range of propagation velocities for a light pulse comprising a range of wavelengths. The material dispersion in optical fibers limits the ‘*bit rate × distance product*’ achievable with LEDs. The spontaneous lifetime of carriers in LEDs in direct-gap semiconductors typically is on the order of 1–100 ns depending on the active region doping concentration (or carrier concentrations) and the material quality. Thus, modulation speeds up to 1 Gbit s^{-1} are attainable with LEDs.

In practice, the emission line-width is usually broader than the theoretical value of $1.8 kT$. A spectral width of $1.8 kT$ is expected for the thermally broadened emission. However, due to other broadening mechanisms, the line-width can exceed the theoretical value. A prominent broadening mechanism among ternary and quaternary III–V alloy semiconductors is *alloy broadening*, i.e., the statistical fluctuation of the active region’s alloy composition. Alloy broadening is independent of temperature and can broaden the line-width to 2 to 5 times of its thermally broadened value. For example, at room temperature, GaInN blue and green LEDs can have a line-width of 3–10 kT .

Figure 3 shows typical LED emission spectra at room temperature. The emission spectra include an AlGaInP/GaAs red, GaInN/GaN green, GaInN/GaN blue, GaInN/GaN UV, and an AlGaIn/AlGaIn DUV LED. The active region of visible-spectrum LEDs is typically comprised of a ternary or quaternary alloy, for example, $\text{Ga}_{1-x}\text{In}_x\text{N}$ or $(\text{Al}_x\text{Ga}_{1-x})_{0.5}\text{In}_{0.5}\text{P}$. An idealized alloy-broadened emission spectrum has a Gaussian lineshape. It may be noted that deep UV LEDs are not yet as mature as visible-spectrum devices. For example, the emission spectrum of the 290 nm device shown in **Figure 3** has a low energy shoulder that is due to an undesired parasitic emission, most likely a defect-related emission.

Figure 2 Theoretical emission spectrum of an LED. The full-width at half-maximum (FWHM) of the emission line is $1.8 kT$.

Figure 3 Emission spectra, at room temperature, of AlGaInP/GaAs red, GaInN/GaN green, GaInN/GaN blue, GaInN/GaN UV, and AlGaInP/GaAs DUV LEDs.

Homostructures and Heterostructures

In the vicinity of the unbiased p–n junction plane, electrons originating from donors on the n-type side diffuse to the p-type side where they recombine, as shown in the band diagram of Figure 4. A corresponding process occurs with holes. As a result, a region near the p–n junction, the *depletion region*, is depleted of free carriers. In the absence of free carriers, the types of charges in the depletion region are ionized donor and acceptor charges. The charges in the depletion region produce a potential, the *built-in potential*, V_{bi} , given by

$$V_{bi} = \frac{kT}{e} \ln \frac{N_A N_D}{n_i^2} \quad [2]$$

where N_A and N_D is the acceptor and donor concentration, respectively, and n_i is the intrinsic carrier concentration of the semiconductor. The built-in voltage represents a barrier that free carriers must overcome in order to reach the neutral region of opposite conductivity type.

The width of the depletion region is given by

$$W_D = \sqrt{\frac{2\epsilon}{e} (V_{bi} - V) \left(\frac{1}{N_A} + \frac{1}{N_D} \right)} \quad [3]$$

where $\epsilon = \epsilon_r \epsilon_0$ is the dielectric permittivity of the semiconductor and V is the diode bias voltage.

An external bias applied to a p–n junction will drop across the depletion region, which is resistive due to the lack of free carriers. A forward bias decreases the p–n junction barrier causing electrons and holes to be injected into the neutral regions with

Figure 4 Free carrier distribution in (a) homostructure under equilibrium conditions, (b) forward-biased homostructure, and (c) forward-biased double heterostructure (DH). $L_{n/p}$ and $\tau_{n/p}$ are the minority carrier diffusion lengths and lifetimes, respectively. W_D is the width of the depletion region. In the forward-biased homostructure, carriers are distributed over the diffusion length ($L_n + L_p$); in a DH, they are distributed over the thickness of the DH (W_{DH}). The carrier confinement provided by the DH reduces SRH recombination.

opposite conductivity type. As the injection current increases, carriers diffuse into the regions of opposite conductivity type and recombine, thereby emitting photons.

The theory of current transport in p-n junctions was first developed by William B. Shockley in the early 1950s and the equation describing the I - V characteristic is known as the *Shockley equation*

$$I = eA \left(\sqrt{\frac{D_p}{\tau_p}} \frac{n_i^2}{N_D} + \sqrt{\frac{D_n}{\tau_n}} \frac{n_i^2}{N_A} \right) (e^{eV/kT} - 1) \quad [4]$$

where A is the junction area and $D_{n, p}$ and $\tau_{n, p}$ are the electron and hole diffusion constants and minority carrier lifetimes, respectively.

Under typical forward bias conditions, the diode voltage is $V \gg kT/e$, and thus $[\exp(eV/kT) - 1] \approx \exp(eV/kT)$. For such forward bias conditions, the Shockley equation can be rewritten as

$$I = eA \left(\sqrt{\frac{D_p}{\tau_p}} N_A + \sqrt{\frac{D_n}{\tau_n}} N_D \right) e^{e(V - V_{bi})/kT} \quad [5]$$

The exponent in the equation illustrates that the current strongly increases as the diode voltage approaches a *threshold*, which is about equal to the built-in voltage, i.e., $V_{th} \approx V_{bi}$.

In an ideal diode, every electron injected into the active region will generate a photon. Thus conservation of energy requires that the electron energy eV equals the photon energy $h\nu$, i.e.,

$$eV = h\nu \quad [6]$$

Beyond turn-on, the diode becomes highly conductive and the diode voltage V is about the same as the threshold voltage V_{th} . The energy of photons emitted from a semiconductor with energy gap E_g is given by

$$h\nu = E_g + (1/2)kT \approx E_g \quad [7]$$

Thus eqn [6] can be rewritten as

$$V_{th} \approx V_{bi} \approx E_g/e \quad [8]$$

For example, a GaAs IR LED emitting at 870 nm has a threshold voltage of about 1.4 V; similarly, a GaInN blue LED has a threshold voltage of about 2.8 V.

Homojunction LEDs have significant drawbacks and hence are no longer used. At the present time, virtually all commercial devices are heterojunction LEDs. Heterojunction active regions have several advantages that will be discussed below.

The effect of a double heterostructure (DH) on the carrier concentration is illustrated in Figure 4. Under forward bias, carriers diffuse across the p–n junction. In the case of a homostructure under forward bias, minority carriers are distributed over the electron and hole diffusion lengths as illustrated in Figure 4(b). In III–V semiconductors, diffusion lengths can be 10 μm or longer. The wide distribution of carriers and the correspondingly low carrier concentration (particularly toward the end of the diffusion tail) can be avoided by the employment of DHs. Carriers are confined to the active region of width W_{DH} , as shown in Figure 4(c). To attain good carrier confinement, the barrier heights should be much greater than the thermal energy kT .

An important advantage of the DH design is illustrated in Figure 5. The DH structure has a much smaller number of defects within the recombination region so that nonradiative SRH recombination via deep levels is much less significant in a DH and in QW active regions. As a result, DH or QW LEDs have a much higher efficiency than homostructure LEDs.

The term ‘DHs’ is frequently used for active layers with thickness of 100 to 500 nm. The term ‘QW’ active region is used for active layers with thickness of 2 to 100 nm. Single quantum well (SQW) and multi-quantum well (MQW) active regions provide additional carrier confinement, which can further improve the internal quantum efficiency. If a MQW active region is used, the barriers between the wells may impede the flow of carriers between adjacent wells. Thus the barriers in a MQW active region need to be sufficiently ‘transparent’ (low and/or thin barriers) in order to allow for efficient carrier transport between the wells and to avoid the inhomogeneous distribution of carriers within the active region.

Another advantage of DH and QW structures is the optical transparency of the barrier layers. That is, the two cladding layers (cladding the active region) have a wider bandgap than the active region. That is, light generated in the active region cannot be absorbed in the cladding layers because their bandgap energy is greater than the photon energy ($E_g > h\nu$).

Light-Extraction in LEDs

Owing to the high refractive index of semiconductors, light incident on a planar semiconductor–air interface is totally internally reflected, if the angle of incidence is sufficiently large. Snell’s law gives the critical angle of total internal reflection. As a result of total internal reflection, light can be ‘trapped’ inside the semiconductor chip. Light trapped in the chip will eventually be reabsorbed, for example, by the substrate, active region, cladding layer, or by a metallic contact.

If the light is absorbed by the substrate, the electron–hole pair will most likely recombine non-radiatively due to the inherently low efficiency of substrates. If the light is absorbed by the active region, the electron–hole pair may re-emit a photon or recombine non-radiatively. For active regions with internal quantum efficiencies of less than 100%, any reabsorption event will reduce the efficiency of the LED. For this reason, light should be coupled out of the LED chip with the shortest possible path length inside the chip.

If the angle of incidence of a light ray is close to normal incidence, light can escape from the semiconductor. However, total internal reflection occurs for light rays with oblique and grazing-angle incidence. Total internal reflection reduces the EQE significantly, in particular for LEDs consisting of high-refractive-index materials.

Assume that the angle of incidence in the semiconductor at the semiconductor–air interface is given by ϕ . Then the critical angle of total internal reflection, ϕ_c , can be inferred from Snell’s law and is given by

Figure 5 In a double heterostructure (or QW structure), the recombination region, and thus the number of defects contained in this region, is much smaller than in a homostructure. Therefore, nonradiative SRH recombination will play a much smaller role in DH active regions (as well as QW active regions).

Figure 6 (a) Illustration of refraction and total internal reflection at a semiconductor–air interface. (b) Definition of the escape cone by the critical angle ϕ_c . Area of calotte-shaped section of the sphere defined by radius r and angle ϕ_c .

$$\phi_c = \arcsin \frac{\bar{n}_{\text{air}}}{\bar{n}_s} \quad [9]$$

The refractive indices of semiconductors are usually quite high. For example, GaAs has a refractive index of 3.4. Thus, according to eqn [9], the critical angle for total internal reflection is quite small. In this case, we can use the approximation $\sin \phi_c \approx \phi_c$. The critical angle for total internal reflection is then given by

$$\phi_c \approx \frac{\bar{n}_{\text{air}}}{\bar{n}_s} \quad [10]$$

The angle of total internal reflection defines the light escape cone, as shown in **Figure 6(a)**. Light emitted into the cone can escape from the semiconductor, whereas light emitted outside the cone is subject to total internal reflection.

Calculating the surface area of the spherical cone with radius r allows one to determine the total fraction of light that is emitted into the light escape cone. The surface area of the calotte-shaped surface is shown in **Figure 6(b)**. The fraction of the light emitted inside a semiconductor can escape from the semiconductor is given by

$$\frac{P_{\text{escape}}}{P_{\text{source}}} = \frac{1}{2} (1 - \cos \phi_c) \approx \frac{1}{4} \frac{\bar{n}_{\text{air}}^2}{\bar{n}_s^2} \quad [11]$$

The escape problem is a significant problem for high-efficiency LEDs. In most semiconductors, the refractive index is quite high ($\bar{n} \geq 2.5$) and thus only a small percentage of the light generated in the semiconductor can escape from a planar LED. The problem is less significant in semiconductors with a small refractive index and for polymers, which have refractive indices of the order of 1.5.

The light escape problem, illustrated in **Figure 7(a)**, has been known since the infancy of LED technology in the 1960s. It has also been known that the geometrical shape of the LED die plays a critical role. The optimum LED would be spherical in shape with a point-like light-emitting region in the center of the LED. Unfortunately, spherical LEDs with a point-like light source in the center of the LED are impractical. Semiconductor fabrication technology is, in view of the flat substrates used in epitaxial growth, a planar technology. Thus spherical LEDs would be exceedingly difficult to fabricate using conventional processing technologies.

More realistic alternatives include the resonant-cavity LED (see **Figure 7(b)**), surface-textured LEDs (see **Figure 7(c)**), and chip-shaped LEDs (see **Figure 7(d)**).

A popular method to increase the light-extraction efficiency is the use of *roughened* or *textured semiconductor surfaces*, first introduced by Bergh and Saul (1973) for GaP-based devices. The authors showed that, at the first instance the light is incident at the semiconductor–air interface, the same amount of light escapes from a rough surface plane as does from a smooth surface plane. However, since the reflections occur at random angles, a similar proportion of light will escape at the second and subsequent instances the light ray is incident on the roughened surface. This is in contrast to a smooth surface plane which preserves reflection angles and thus traps the reflected light. **Figure 8(a)** illustrates the enhanced out-coupling of a light ray through a roughened surface.

GaN textured surfaces created by crystallographic etching (Stocker *et al.*, 1998) are very well suited to enhance light extraction. Several publications reported an increase in light extraction in GaN-based LEDs with surface texturing achieved by crystallographic wet chemical etching (Gao *et al.*, 2004; Fujii *et al.*, 2004; Jung *et al.*, 2010; Horng *et al.*, 2011). The strongly textured GaN surfaces shown in **Figure 8(b)** reveal the exposure of a variety of crystal planes that are indicative of a crystallographic etch (Haerle, 2004; Jung *et al.*, 2010).

White LEDs

High-efficiency red, orange, and yellow devices (AlGaInP LEDs) had been developed in the 1980s. High-efficiency violet, blue, and green devices (GaInN LEDs) had been developed in the 1990s. Therefore, in the mid-1990s monochromatic high-efficiency devices, covering the entire visible spectrum, were available. As a result, the generation of white light by LEDs had been enabled. There are several approaches for white LEDs:

Figure 7 (a) Light rays emanating from a point-like emitter are trapped inside the semiconductor due to total internal reflection. Only light rays with propagation directions falling within the escape cone can leave the semiconductor. Strategies increasing the extraction efficiency include the (b) resonant-cavity LED, (c) surface-textured LED, and (d) die-shaped LED.

Figure 8 (a) LED chip with roughened surface enabling out-coupling of light (after Bergh and Saul, 1973). (b) Scanning electron micrograph (SEM) of N-face GaN surface after crystallographic wet chemical etching using a KOH-solution (after Jung *et al.*, 2010).

A *first* approach is a multi-LED approach in which the light from multiple LEDs emitting different colors is mixed to create white light. This approach became feasible with the demonstration of highly efficient blue and green LEDs (Nakamura *et al.*, 1994,1995). Nakamura *et al.* (1995) stated: "By combining high-power and high-brightness blue InGaN SQW LED, green InGaN SQW LED and red GaAlAs LED, many kinds of applications, such as LED full-color displays and LED white lamps for use in place of light bulbs or fluorescent lamps, are now possible with characteristics of high reliability, high durability and low energy consumption."

A *second* approach is a UV-LED-plus-multi-color-phosphor combination (Baretz and Tischler, 2003). However, this approach suffers from a lower efficiency compared with the multi-LED approach since UV light is converted to visible light whereby a significant fraction of the energy is being lost. We note that this approach is similar to a conventional fluorescent lamp; in both cases UV light is converted into visible light by means of a phosphor.

A *third* approach is a blue-LED-plus-yellow-phosphor combination. This approach is most efficient and most successful. Due to the complementary nature of blue and yellow light, white light can be created by the mixture of blue light from an LED chip, and yellow light from a yellow phosphor. Cerium-doped yttrium-aluminum garnet phosphor (Ce-doped YAG), a stable and highly

Figure 9 (a) White LED lamp consisting of a GaInN blue LED chip and a yellow YAG:Ce phosphor. (b) Blue luminescence and wavelength-converted yellow fluorescence (after Nakamura and Fasol, 1997).

efficient yellow phosphor, was first used for a white LED by Bando *et al.* (1996, 1998), as further described by Nakamura and Fasol (1997) and Shimizu *et al.* (1999).

The third approach evolved into a pervasive commercial success, in part due to its efficiency, simplicity, and the requirement of only one LED chip driven by only one power supply.

Indeed, on September 13, 1996, a new era in lighting began: An article in the Japanese newspaper *Nikkei* (1996) announced a new type of white light LED, based on a blue LED chip and a yellow Ce-doped YAG phosphor, as shown in Figure 9. The white LED was reported to be efficient (5 lm W^{-1}), low cost, and have a predicted lifespan of 50 000 h. What was announced in a relatively short newspaper article was a novel light source that was set to revolutionize the world of lighting.

In October 1996, full-scale production of the phosphor-converted white LED started at the Nichia Company in Anan, Japan. On November 29, 1996, technical details of Nichia's white LED were presented at a technical meeting of the Institute of Phosphor Society (Japan) and the associated 264th Proceedings of the Institute of Phosphor Society (Japan). The emission spectrum of the first phosphor-converted white LED is shown in Figure 10 (Bando *et al.*, 1996). The emission spectrum is continuous covering nearly the entire visible wavelength range. Compared with the 'spiky' emission spectrum of the then-common compact fluorescent lamps (CFLs), the quality of the white light emitted by the LED was superior. Likewise, compared with the power consumption of the then-common incandescent light bulbs, the prospect of white LEDs, in terms of power consumption, was far superior. Thus, the foundation of a new LED white light source, that was poised to replace conventional white light sources, had been established.

Whereas organic phosphors (dyes having carbon ring molecules) had been initially used to generate white light, these organic phosphors simply were not sufficiently stable: When subjected to the high optical radiation density of an LED chip, the double bonds of the organic phosphor molecules break thereby degrading the phosphor molecule (frequently containing aromatic rings). The first successful and commercially viable white LED was based on a yellow garnet phosphor, $\text{Y}_3\text{Al}_5\text{O}_{12}$ doped with the optically active element Ce. Such YAG:Ce phosphors are characterized by (1) an optical absorption band in the blue spectral range, (2) an emission band that has a peak wavelength of about 550–580 nm, (3) high chemical stability, (4) high stability under high optical irradiance as encountered in proximity of a high-brightness blue LED chip, (5) short radiative lifetime (about 50–80 ns), and (6) tunability of the optical emission spectrum by chemical modifications of the YAG host material, for example, the substitution of Y atoms by Gd atoms and of Al atoms by Ga atoms yielding a phosphor with the general formula $(\text{Y}_{1-x}\text{Gd}_x)_3(\text{Al}_{1-x}\text{Ga}_x)_5\text{O}_{12} : \text{Ce}$. These favorable characteristics have made YAG:Ce the phosphor of choice for white LEDs.

At the present time, 'phosphor blends' are frequently employed. Such phosphor blends are a mixture of multiple phosphor materials. Common phosphors include the YAG:Ce family of phosphors, Eu-doped silicate phosphors emitting in the green spectral range and Eu-doped nitride phosphors emitting in the red spectral range. Figure 11 shows typical emission spectra of white LEDs with low, medium, and high color temperatures. As the color temperature of the light source is decreased, (1) the relative phosphor emission increases and (2) a red phosphor with a peak wavelength of about 600–650 nm is added.

The temporal evolution of the luminous efficiency of light sources is shown in Figure 12. The figure shows the following light sources: Incandescent lamp with C filament demonstrated in 1879 by Thomas A. Edison; Incandescent lamp with ductile W filament demonstrated in 1911 by William D. Coolidge; Linear fluorescent lamp (LFL) introduced in 1937 at the New York World's

Figure 10 Emission spectrum of first phosphor-converted white LED. The LED consists of a GaInN blue LED chip and a YAG:Ce yellow phosphor (after Bando *et al.*, 1996).

Figure 11 Emission spectra of phosphor-converted white LEDs having a low, medium, and high correlated color temperature (CCT). The relative intensities of the LED-chip emission and the phosphor emission allow one to tune the CCT within the ranges indicated.

Figure 12 Temporal development of the luminous efficiency of different types of lamps. The 2014 points represent: (1) White LED device performance (Cree Company, 2014; 303 lm W^{-1} ; CCT = 5150 K), and (2) White LED device and system performance (Osram Company, 2014; 215 lm W^{-1} (device); 205 lm W^{-1} (system); CCT = 3000 K).

Fair; CFL introduced in 1985 by Osram Company (after Kane and Sell, 2000). These conventional light sources and their typical efficiencies are as follows:

- Incandescent light bulb with C (carbon) filament: 1.2–2 lm W^{-1}
- Incandescent light bulb with W (tungsten) filament: 10–18 lm W^{-1}
- Incandescent halogen light bulb with W (tungsten) filament: 16–24 lm W^{-1}
- LFL: 65–95 lm W^{-1}
- CFL: 50–70 lm W^{-1}

In 2010, reported efficiencies of white LEDs were in the 150–250 lm W^{-1} range. Very high efficiencies were reported by several companies including the following: Nichia Company's Takashi Mukai announced a laboratory-result efficiency of 249 lm W^{-1} for a white LED injected with a low current (Mukai, 2009). The Cree Company announced a laboratory-result efficiency of 208 lm W^{-1} for a white LED with a CCT of about 4600 K at an injection current of 350 mA (Cree, 2010). On March 26, 2014, the Cree Company announced a laboratory-result efficiency of 303 lm W^{-1} for a white LED lamp (excluding power supply) with a CCT of 5150 K at an injection current of 350 mA (Cree, 2014). On March 28, 2014, the Osram Company announced a lamp efficacy of 215 lm W^{-1} and a system efficiency (including power supply) of 205 lm W^{-1} for a white LED lamp system with a color temperature of 3000 K (Osram Company, 2014).

DUV LEDs

III-Nitrides compound semiconductors such as AlN, GaN, and InN, and their alloys are known to produce light in a wide range of wavelengths from the near infrared, through the visible, down to the ultraviolet spectral range. The $\text{Ga}_{1-x}\text{In}_x\text{N}$ -based blue-LED-plus-yellow-phosphor combination has evolved into a commercial success for highly efficient, environmentally friendly white light sources for general illumination. $\text{Al}_x\text{Ga}_{1-x}\text{N}$ -based LEDs, covering the wide range of DUV wavelengths from about 360 nm (GaN) down to 210 nm (AlN), become increasingly attractive due to their promising potential in applications such as purification of air and water, sterilization in food processing, disinfection in hospitals, and medical applications (Khan *et al.*, 2007; Shur and Gaska, 2010). The promise of $\text{Al}_x\text{Ga}_{1-x}\text{N}$ DUV LEDs goes far beyond just replacing the mercury lamps in existing applications and includes the creation of new market opportunities.

However, the reported EQE values of $\text{Al}_x\text{Ga}_{1-x}\text{N}$ DUV LEDs are low, and decrease almost exponentially with increasing Al molar fraction x , as shown in Figure 13. The reasons for the decrease are related to intrinsic material properties of AlGaN: *Firstly*, increasing the Al composition generally leads to a high density of extended defects such as dislocations, grain boundaries, and cracks in the $\text{Al}_x\text{Ga}_{1-x}\text{N}$ epilayer, which results in poor internal quantum efficiency. *Secondly*, doping, especially p-type doping, of $\text{Al}_x\text{Ga}_{1-x}\text{N}$ films becomes difficult because the ionization energy of acceptor dopants (Mg) increases with Al composition (~ 170 meV for GaN, ~ 630 meV for AlN), which causes multiple additional problems including (1) poor ohmic contact properties for both n- and p-type AlGaN thereby causing a high operating voltage, (2) poor hole-injection efficiency into the active region, and (3) high resistivity of the AlGaN layer causing non-uniform current injection into the active region, also referred to as 'current crowding' (Guo and Schubert, 2001). Although a p-type GaN layer is typically used as a contact and a hole-supplying layer to overcome (1) and (2), it causes poor light-extraction efficiency due to a strong absorption of UV photons by the p-type GaN. *Thirdly*, the light-extraction efficiency in AlGaN DUV LEDs grown on c-plane sapphire substrates is severely limited by strong TM-polarized anisotropic emission due to the unique valence band structure of $\text{Al}_x\text{Ga}_{1-x}\text{N}$ for $x > \sim 0.25$ in which the topmost valence band is the crystal-field split-off hole band having a P_z -orbital-like property (Taniyasu and Kasu, 2010). Conventional light-extracting-enhancing techniques, such as surface texturing and substrate patterning, favor extracting TE-polarized light, and thus have a negligible effect on AlGaN DUV LEDs. Accordingly, this calls for a totally new approach to deliver a real breakthrough in light extraction.

Despite the challenges originating from intrinsic material properties of AlGaN, impressive research efforts in the development of AlGaN DUV LEDs have advanced the EQE from less than 0.1% to about 1 ~ 10% (depending on the emission wavelength) over the past 10 years. Various growth techniques including pulsed atomic-layer epitaxy and high-temperature growth, and stress-managing techniques such as the use of AlN/AlGaN superlattices (SLs) resulted in a strongly reduced dislocations density and crack formation, and thus enhanced internal quantum efficiency.

Figure 13 Maximum external quantum efficiencies (EQEs) attained by various research groups as compiled by Kneissl (2015), and acceptor activation energy and corresponding hole concentrations, and reported values of degree of polarization (Northrup *et al.*, 2012)

Another critical area that is in need of a major improvement is the p-type doping of AlGaIn. One alternative way to achieve a highly conductive p-type AlGaIn is to grow SLs that have been shown to enhance the free hole concentration in AlGaIn by a factor of 10 (Goepfert *et al.*, 2000). The band modulation of SLs along with the modulation caused by the polarization fields enables a higher acceptor ionization ratio and thus a higher hole concentration. Another proposed alternative to overcome the p-type doping problem is the injection of holes by means of a polarization-charge-enhanced tunnel junction (Schubert, 2010). According to this concept, polarization-charge-enhanced tunnel junctions can improve the hole-injection efficiency by enabling a p-side-down structure and even reduce optical absorption in the p-type GaN contact layers. Finally, a new light-extraction-enhancing approach has been proposed to utilize the inherently strong TM-polarized light emitted from the AlGaIn active region (Kim *et al.*, 2015). The side-emission-enhanced DUV LEDs show better electrical properties as well as much enhanced light output power with a strongly upward-directed emission due to an exposed sidewall of the active region and Al-coated selective-area-grown n-type GaN micro-reflectors.

Oto *et al.* (2010) proposed an alternative way to realize a highly efficient DUV emitter based on electron-hole generation by means of electron-beam excitation. In contrast to p-n junction devices (like an LED), electron-beam excitation uses highly accelerated electrons to generate electron-hole pairs inside the target material. At an acceleration voltage of 8 kV, a maximum power efficiency of 40% was reported for 240 nm emission; this is remarkable given the much lower efficiencies attained by conventional p-n junction DUV LEDs emitting at similar wavelengths.

LED Packaging

Virtually all LEDs are mounted in a package that provides two electrical leads, a transparent optical window for the light to escape, and, in high-power packages, a thermal path for heat dissipation. The chip-encapsulating material advantageously possesses high optical transparency, a high refractive index, chemical inertness, high-temperature stability, and hermeticity. The refractive index contrast between the semiconductor and air is reduced by including an encapsulant thereby increasing the light-extraction efficiency. Virtually all encapsulants are polymers with a typical refractive index of about 1.5 to 1.8. The reduced index contrast at the semiconductor-to-encapsulant interface increases the critical angle for total internal reflection thereby enlarging the light escape cone and the light-extraction efficiency.

A *low-power package* is shown in Figure 14(a). The LED chip is die-bonded (e.g., attached by means of an adhesive) to the bottom of a cup-like depression ('reflector cup') located in one of the lead terminals (usually the cathode terminal). A bond wire connects the LED top contact to the other lead terminal (usually the anode terminal). The LED package shown in the figure is frequently referred to as a 'radial,' a '5 mm' or 'T1-3/4' package.

In low-power LEDs, the encapsulant has the shape of a hemisphere, as shown in Figure 14(a), so that the angle of incidence at the encapsulant-air interface is always normal. As a result, total internal reflection does not occur at the encapsulant-air interface. There are types of LEDs that do *not* have a hemispherical shape for the encapsulant. Some LEDs have a rectangular or cylindrical shape with a planar front surface.

A *high-power package* is shown in Figure 14(b). High-power packages have a *direct, thermally conductive path* from the LED chip, through a heat-sink, to, for example, a printed circuit board with a metal core. The high-power package shown in the figure has several advanced features. Firstly, the package contains an Al or Cu heat-sink slug with low thermal resistance to which the LED submount is attached by means of a metal-based adhesive material. Secondly, the chip is encapsulated with silicone. Because standard silicone retains mechanical softness when cured, the silicone encapsulant is covered with a plastic cover that also serves as lens. Thirdly, the chip is directly mounted on a Si submount that includes electrostatic discharge (ESD) protection.

Generally, packaging processes are associated with high costs. During the front-end epitaxial-wafer processing stage, many LED chips are processed at the same time (there are thousands of LED chips per epitaxial wafer). However, during the back-end

Figure 14 (a) Traditional LED package having radial miniature lamp configuration. (b) High-power surface-mount LED package having a dedicated heat path by means of a heat-sink slug.

Figure 15 High-power LED package having a ceramic substrate for improved heat sinking and a dedicated thermal pad that is electrically insulated from the anode and cathode contact (adapted from Luxeon Rebel blue and white LED of the Philips Lumileds Company; Philips, 2014).

packaging process, packages may be processed one-at-a-time. Accordingly, the packaging process is a serial process and thus expensive. To reduce costs, the LED packaging process is ‘parallelized,’ that is, arrays of packages are processed, for example, in a 10×15 array. As one of the final steps in the process, the array of LED packages is ‘singulated,’ i.e., separated into single devices.

A singulated LED package is shown in Figure 15 (Luxeon Rebel blue and white LED of the Philips Lumileds Company; Philips, 2014). Inspection of the figure shows that the chip is mounted on a ceramic substrate. The ceramic substrate was originally an element of an array of devices that was singulated, for example, by sawing the ceramic board on which the array of devices is located. Ceramics have a high thermal conductivity that is close to that of metals. For example, AlN and Al have a thermal conductivity of $170\text{--}190$ and $205\text{--}250\text{ W m}^{-1}\text{ K}^{-1}$, respectively.

History and Background

In the late 1950s Alvin Van Valkenburg at the National Bureau of Standards (now the National Institute of Science and Technology) reasoned that he could make infrared absorption measurements on a sample under pressure by squeezing the sample between the flat faces of two diamond anvils. He did not know if the faces were perfectly parallel and so he placed his device on the stage of a microscope and looked through the diamonds at the sample. When he saw the sample, he immediately realized that he had something extraordinary. Although the diamond faces were in fact not very parallel, he could see that parts of the sample looked different because they were at high pressure (HP); and the diamond anvil cell was born. Visual observation continues to the present as the most important technique used with DACs. Van Valkenburg found that he could solidify water, alcohol, and other liquids by placing them in gaskets formed by drilling holes in metal foils and placing them between the diamond faces. He also found he could see phase transitions in single crystals of calcite and other solids when surrounded by a fluid in a gasket. The National Bureau of Standards group soon found they could examine samples under pressure by X-ray diffraction as well.

Since that time there have been more than a dozen additions to the list of analytical techniques successfully used to study samples at high pressures and temperatures (HPT) in the DAC. These include a variety of applications employing visible light, infrared, X-rays, electrical resistance, and magnetic susceptibility.

Principles of the Diamond Anvil Cell

Diamond has many properties that make it ideal for use as anvils in HP devices. It is the hardest material known, has elastic moduli with very large values, is transparent to large portions of the electromagnetic spectrum, is a good electric insulator, is an excellent thermal conductor, and is readily available as nearly perfect single crystals. Gem diamonds are available in high-quality, ready-cut shapes close to the most desirable shapes for anvils. Grinding and polishing the culet point on a brilliant-cut faceted diamond is all that is needed to turn it into an anvil face. Although metastable, diamond has a remarkable resistance to change with increased pressure and temperature up to hundreds of GPa and ~1500 K. Recently developed transparent polycrystalline diamond anvils have some valuable advantages in the pursuit of HP high-temperature research. See 'Recent Advances' below.

[☆]*Change History:* April 2015. W. Akers Bassett added the following new subsections under 'Recent Advances' above and references to this section are made throughout the text: (1) Gasketless Sample Mounting, (2) Polycrystalline Diamond Anvils, (3) The Push to Ever Higher Pressures, and (4) Diffraction Peaks in X-ray Absorption Spectra. The following figures have been added: (1) Figure 12 showing gasketless configuration, (2) Figure 13 showing two-stage diamond anvil cell, and (3) Figure 14 showing analytical techniques used with DACs.

Figure 1 The diamond anvil cell (DAC) consists of two gem diamonds with their culet points ground and polished to form anvil faces. The diamonds are driven together against a sample contained in a gasket consisting of a hole drilled in a foil. This very versatile principle allows a wide variety of configurations depending on the type of analytical technique being applied.

Great versatility is possible because the principle of the diamond anvil cell is simple: two diamond anvils driven together with a sample trapped between them (**Figure 1**). Because pressure is defined as force divided by area, it can be increased by increasing force or decreasing area. The DAC clearly benefits from the latter. As analytical techniques have become miniaturized, diamond anvil faces have been reduced to dimensions only microns across while forces continue to be generated by screws, levers, and small hydraulic or pneumatic devices. Because such small anvil faces are needed for generating very HPs, precise parts with precise motions are essential for maintaining alignment. DACs need good support for the anvils, usually a hard material such as tungsten carbide or a ceramic such as Si_3N_4 , while providing adequate access for analytical techniques, usually an opening in the support and/or in the plane of the sample. The principle is so simple that DACs can be adapted to the geometric needs of many analytical techniques. As a result, there are numerous DAC designs.

Gaskets

Gaskets play an important role in the many applications of DACs. The properties of gasket materials are crucial and are selected for specific applications. The rheologic properties of gasket materials are usually the most important. However, transparency to X-rays, electrical properties, and chemical properties are important as well. Gasket materials include rhenium, tungsten, iridium, spring steel, inconel, stainless steel, brass, boron–epoxy mixture, aluminum, and beryllium. Recently fluid samples have been sealed in a sample cavity in one of the diamond anvils by pressing the flat anvil faces together, i.e., with no gasket. See ‘Recent Advances’ below.

Heating a Sample in a DAC can be Achieved by

1. external resistance heating including use of heaters that surround the whole cell, heaters that surround just the anvils, heaters that surround the seats that the anvils sit on (**Figure 2**), and graphite heaters that are imbedded within the anvils;
2. internal resistance heaters are heaters that are insulated from the anvils and therefore do not heat the anvils to temperatures as high as sample temperature (**Figure 3**). They consist of an electrically conducting sample wire, a metal strip with a hole to receive the sample, or graphite sandwich; and
3. laser heating also heats the sample without heating the anvils (**Figure 4**).

External resistance heating (**Figure 2**) requires careful choice of materials that will resist softening or deformation with temperature change. Because some of the materials, including diamond, readily oxidize at high temperature, an inert or slightly reducing gas is needed to prevent oxidation. The main advantage of external heating is the very constant and uniform temperatures that can be achieved. Pressures can also be held constant when the cell is designed to eliminate or minimize the effects of dimensional changes with temperature. Pneumatic devices and springs that are kept cool are especially important for achieving this. The main disadvantage is the upper limit of 1500 K at which diamond begins to graphitize.

Internal resistance heating (**Figure 3**) has the advantage that it heats only the sample and can, therefore, generate much higher temperatures than can be tolerated by the diamond anvils. The upper limit for internal resistance heating is imposed by the melting point of the resistor. However, that can be very high if Re or W is used.

Figure 2 Samples can be heated to 1500 K while under pressure by means of resistance heaters wound around the seats supporting the diamond anvils. Thermocouples placed in contact with the diamond anvils measure temperatures to within a few kelvin. Corrections can be made by observing melting of standard materials in the sample chamber. Access can be through the diamonds or the gasket.

Figure 3 An internal resistance heater, usually constructed from rhenium, can be used to heat a sample to much higher temperatures (3000 K) than the diamonds can tolerate because it is insulated from them. Temperatures are measured by spectroradiometry.

Laser heating (**Figure 4**) has employed yttrium aluminum garnet (YAG), yttrium lithium fluoride (YLF), and CO₂ lasers with their beams focused through the anvils onto the sample. The sample must be thermally insulated from the diamond anvils by a transparent material, which protects the diamonds and serves as a pressure medium. Although continuous power delivered to both sides of the sample has yielded the best quantitative results, single-side and pulsed laser heating have been used extensively to overcome kinetic barriers and promote phase transitions. Temperatures of thousands of kelvin can be achieved, especially if very short pulses are used. Sample design for laser heating is much simpler than for internal resistance heating, but requires a rather large and complex optical system outside of the DAC.

Figure 4 Laser heating can raise the temperatures of samples to several thousands of kelvin. When a laser beam is split and directed to the sample through both anvils, more uniform and constant temperatures can be achieved than heating from one side alone. Temperature gradients within the sample are minimized by using the larger TEM₀₁ laser mode and focusing the probing X-ray beam to a very small spot within the heated area.

Low temperatures down to that of liquid helium can be achieved by passing cold gases through the DAC or injecting liquid nitrogen or liquid helium directly into the cell and letting it boil there. Another approach has been to completely immerse the DAC into liquid nitrogen or liquid helium.

Pressure Measurement

Accurate methods for determining pressure can be divided into two groups: (1) primary, those that are independent and (2) secondary, those that must be calibrated using a primary pressure scale.

Primary Pressure Measurement

Force divided by area can provide reliable, accurate pressure measurements but only if the pressure over the area is uniform as in piston-cylinder apparatus. However, piston-cylinder apparatus cannot generate pressures anywhere near what is possible using DACs. Phase transitions such as those in elemental bismuth were used as calibration points for transferring pressure measurements to other types of apparatus in which those same phase transitions could be observed.

One of the most significant advances was Decker's development of an equation of state (EoS) for NaCl from first principles. This could be applied directly when X-ray diffraction (XRD) was used and NaCl was mixed with the sample in a DAC. Its use for calibrating secondary pressure scales, such as the ruby fluorescence scale, was also very valuable.

Dynamic shock-wave measurements are also an important source of primary pressure determination but rely on corrections when data are converted from high-temperature Hugoniot measurements to isothermal EoS. Nonetheless, dynamic measurements on some metals have provided an important means for calibrating the secondary pressure scales, especially the ruby fluorescence scale, to higher pressures.

Recent primary pressure scales have been based on combining data from direct compression measurement using XRD and sound velocity measurements, which yield data related to the pressure derivative of compression. From the two sets of data, it is possible to derive completely independent values of pressure as a function of lattice parameters. Brillouin scattering in the DAC and sound interferometry have been used to measure sound velocities.

Secondary Pressure Measurement

A secondary pressure scale is one that offers an observable change as a function of pressure. There are many materials which display observable phase transitions at calibrated pressures – Bi, AgI, KCl, and NaCl, to mention a few. One or two of these can be included along with a sample as a pressure indicator. There are many materials whose EoS have been calibrated so that a measurement of their lattice parameters by XRD can be used for determining pressure. Sometimes the sample itself can be used in cases where its EoS is well defined and some other property is being investigated.

The most widely used secondary pressure scale is the ruby fluorescence scale. Ruby, when excited by some higher energy radiation, emits R1 and R2 peaks in the red end of the visible spectrum that shift monotonously with pressure. The fluorescence is typically excited by an argon ion laser and the emission is analyzed by a grating spectrometer. The positions of the R1 and R2 lines in

the spectrum provide a convenient and inexpensive method for determining pressure. In addition, broadening and separation of the R1 and R2 peaks can be used as indicators of deviatoric stress and pressure gradient. Other fluorescent materials such as Cr: MgO and Sm:YAG have been used as well, but ruby continues to be the most popular.

Raman spectra of diamond show shifts with pressure and can be used as a secondary pressure scale. At lower pressures, diamond particles synthesized from ^{13}C are used to avoid interference from the diamond anvils. At higher pressures, natural diamond can be used.

Recent advances in DAC design have led to dramatic increases in sustained pressures that DACs are capable of achieving. Recent reduction of the size of samples that instrumental methods are capable of analyzing has provided a strong incentive to develop new DAC designs. See 'Recent Advances' below.

Temperature Measurement

Temperature measurements in externally heated DACs can be accomplished by placing thermocouples in contact with the diamond anvils. Because diamonds are such good thermal conductors, discrepancies between sample temperature and thermo-couple temperature are rarely more than a few degrees celsius even at the highest temperatures. Corrections to thermocouple readings can be determined by observing melting of standard materials such as NaNO_3 and NaCl placed in the sample chamber. The same thermocouples used for high-temperature measurements can be used for the low-temperature measurements.

Internal resistance heating and laser heating are utilized in order to achieve temperatures in excess of those that cause damage to the diamond anvils ($\sim 1500\text{ K}$). The most commonly used method of temperature determination is spectroradiometry, which consists of fitting the spectrum of incandescent light from the hot sample to a blackbody or graybody curve. Steep temperature gradients and unknown emissivities can be sources of error. However, there are ways to correct for these errors.

Recently, the intensity ratio of stokes and anti-stokes peaks in X-ray Raman spectra has been used to determine temperatures. They were found to be in good agreement with those determined by spectroradiometry.

Pressure Measurement at High Temperatures

Primary Pressure Measurement at High Temperature

Accurate pressure measurement in samples at high temperature has been an area of much concern. Neither sample pressure (isobaric) nor sample volume (isochoric) can be assumed to remain constant as temperature is changed in most sample configurations. In these cases, an internal calibrant is needed. Decker's EoS for NaCl is a full EoS including the effect of temperature on molar volume and is, therefore, suitable for pressure measurement at high temperature. The full EoS of gold has also been determined and is desirable for samples in which only a small amount of pressure calibrant is wanted or where recrystallization needs to be avoided.

There are two configurations, however, that can greatly reduce or eliminate the effect of temperature on pressure. A very small opaque sample surrounded by a much larger volume of transparent pressure medium can be locally heated by laser and remain nearly isobaric because of the relative sizes. Isochoric conditions can be achieved at relatively low pressures by cycling a sample in a gasket, such as rhenium, to high temperature several times. If forces are not great, the gasket finishes relaxing on about the third cycle and the sample volume can be shown to remain constant with temperature within experimental error. If the full EoS of the contents is known, as with H_2O , the pressure can be calculated from the temperature. This approach has been especially valuable in fluid studies where the pressure is allowed to develop as a result of heating.

Secondary Pressure Measurement at High Temperature

Attempts to use ruby and Sm:YAG to measure pressure at high temperature have been less than satisfactory. The fluorescence emission from ruby fades with temperature and the emissions from Sm:YAG are complex to follow. There are several rapidly-running reversible phase transitions that have been calibrated, for example, BaTiO_3 , PbTiO_3 , $\text{Pb}_3(\text{PO}_4)_2$, and transition in quartz. These have specific trajectories in P-T space and, therefore, are not useful for determining pressure at just any location in the P-T space. They are, however, very useful for calibrating fluid EoS described above. Re and other metals have been calibrated for pressure measurement at very high temperatures using XRD.

Analytical Methods

Visual observation is the easiest and most useful method for studying a sample in a DAC. It requires only using a microscope to look at it through the diamond anvils. Visual observation is valuable for not only alignment and centering but can be used to observe phase transitions, coexistence of phases, and optical properties. Phase diagrams can be developed by observing phases as P and T are changed.

Figure 5 The most commonly used configuration is to pass electromagnetic radiation through one diamond anvil to the sample and to observe or analyze the radiation emerging through the other diamond anvil.

XRD of samples under pressure has been one of the most important applications of DACs. Angle dispersion X-ray diffraction (ADXRD) using monochromatic radiation and energy-dispersion X-ray diffraction (EDXD) using white radiation are both used, usually by passing an X-ray beam through one anvil to the sample and collecting scattered X-rays through the other anvil (Figure 5). X-rays that pass through a transparent gasket can also be collected (Figure 6). Both polycrystalline and single-crystal samples can be studied. The advent of synchrotron radiation (SR) with its high intensities, very smooth white spectrum, and excellent collimation has reduced exposure times by orders of magnitude while improving resolution and offering a greater variety of configurations. Improved solid-state detectors have also played a major role.

Emitted visible light from a sample in a DAC can be spectrally analyzed. Fluorescence emission may be excited by X-rays, ultraviolet light, or visible light of shorter wavelength. The trajectory of an X-ray beam as it passes through a fluorescent diamond can be located visually by emission of visible light. The ruby method for determining pressure depends on the excitation of fluorescent emission in small ruby chips included in a sample. Incandescent light from a hot sample contained in a DAC can be spectrally analyzed and fit to a blackbody curve to determine the temperature. Sample fluorescence has been an important source of fundamental information, especially for studying the effect of pressure and temperature on organic compounds. Lasers are favored for stimulating fluorescence because of their high intensity and because they make it possible to pinpoint parts of the sample.

Absorption spectra of light passing through a sample (Figure 5) as well as spectra of reflected light (Figure 7) provide useful information about bonding and band gap changes as a function of pressure and temperature. Imaging can allow selected portions of a sample to be analyzed.

Infrared (IR) absorption spectroscopy requires carefully selected diamonds (usually type II) to be transparent over the desired range of IR-active frequencies. IR absorption at HP has been especially important for understanding the effects of pressure and temperature on organic materials.

Raman scattering has been a very important analytical technique for HPT samples. Light scattered from the sample can be analyzed to determine Raman active vibrational frequencies. Vibrational frequencies are an important source of information for identifying phases, examining bonding, and studying the relationships between vibration frequencies and phase transitions. Hyper-Raman spectroscopy employs a three-photon process and can detect not only far IR vibrational frequencies but can also detect frequencies ('silent' modes) that are not normally IR or Raman active.

Figure 6 Gasket materials transparent to X-rays such as beryllium and boron–epoxy mixture allow incident X-rays to enter through one side of the gasket and scattered X-rays to be collected through the other side.

Figure 7 Observation and analysis of radiation scattered back through the same diamond it entered provide an important source of information for many types of studies.

Figure 8 Brillouin scattering can be used to determine phonon velocities in high-pressure samples without making corrections for refractive indices if the anvil faces bisect the 90° angle between the incident and scattered light rays.

Brillouin scattering has been an important source of information on the effects of P and T on the elastic properties of single-crystal samples. A light beam from a laser, usually an Ar^+ laser, is directed through one of the diamond anvils onto an oriented single-crystal sample in a DAC. Light scattered by interaction with phonons in the sample contains frequency shifts (usually smaller than in Raman spectra) that can be used to calculate the velocities of the phonons. If the anvil faces exactly bisect a 90° angle between the incident beam and scattered light, no corrections need to be made for the refractive index of the sample, medium, and anvils (Figure 8). These phonon velocities, in turn, can be used to determine the effects of P and T on elastic moduli.

Impulsive stimulated scattering (ISS) is another technique that yields information about sound velocities and elastic moduli. Sound waves in the ISS method are generated within the sample by means of laser radiation. Laser light from a different source is Bragg reflected from these sound waves. Its intensity fluctuation can then be used to determine sound velocities.

X-ray spectroscopy (XRS) which includes emission, absorption, and scattering is an area of active development of new techniques and applications in HPT research. X-ray emission spectroscopy (XES) consists of analyzing spectra of radiation excited by an incident X-ray beam as it passes out through the anvils (Figures 5 and 7) or the gasket (Figure 6). Laser-machined diamond anvils and very transparent gaskets are two modifications that now make it possible to analyze all elements heavier than Ca. While elemental analysis is the most important application, newly developed sub-eV energy resolution makes it possible to show a line shape which can be used to provide valuable information on filled electronic states as well as valence and magnetic states such as high-spin to low-spin transition in Fe.

X-ray absorption spectroscopy (XAS) consists of analyzing the spectra of photons absorbed when their energies exceed the excitation energy of deep-core electrons. Laser-drilled holes in the diamond anvils (Figure 9) can reduce the amount of diamond in the beam to 0.3 mm. In these DACs, X-ray absorption fine structure (XAFS) spectra down to 4 keV permit analyses of the K edges of elements as light as Sc as well as L edges of rare-earth elements. Near-edge X-ray absorption fine structure (XANES) provides information on the symmetry-projected conduction band density of states (DOS), while the extended X-ray absorption fine structure (EXAFS) provides local structure information. These element-specific probes are able to reveal electronic and structural changes that take place at HPT conditions.

Figure 9 Holes laser-drilled to within 0.15 mm of the anvil face greatly reduce the absorption by diamond allowing X-ray absorption studies to be made at energies down to 4 keV.

An alternative and very successful way of obtaining absorption spectra is by measuring the intensity of fluorescence emission at the energy of one of the emission peaks while the energy of the incident beam is scanned over the absorption edge being studied. X-rays emerging through an X-ray transparent gasket (**Figure 10**) or side of one of the anvils (**Figure 11**) are collected and analyzed. The signal-to-noise ratio is much improved with this method due to reduced intensity of Rayleigh scattering at 90° to the X-ray beam.

Nuclear resonance X-ray spectroscopy (NRXS), also known as Mössbauer spectroscopy, deals with exceedingly narrow absorption peaks resulting from nuclear transitions. NRXS uses an in-line high-resolution monochromator (HRM) on an SR beam capable of narrowing the photon energy and fine-tuning the monochromatic X-ray beam with meV resolution. Avalanche photodiodes (APD) are used to collect signals from nuclear resonance absorption, and reject all other signals. HRM monochromators have made it possible to extend the Mössbauer method to other elements besides iron that have suitable isomer transitions.

Inelastic X-ray spectroscopy (IXS) represents a major breakthrough for HP research. As in Raman spectroscopy, the energies of the events being probed appear as differences in the energies of incident and scattered X-rays. For this reason, IXS is sometimes referred to as X-ray Raman spectroscopy. This principle makes it possible for experimenters to select X-ray energies that are high enough to easily penetrate diamond anvils and/or low-Z gaskets while probing low-energy phenomena. Recent advances in focusing of X-rays onto samples as small as 0.01 mm and dramatic improvements in monochromators and analyzers to achieve sub-eV resolution

Figure 10 X-ray emission excited by an X-ray beam passing through one of the diamond anvils can pass out through a transparent gasket and be analyzed. Background due to Rayleigh and Compton scattering is minimized when the detector is located at 90° from the X-ray beam in the plane of polarization of an X-ray beam from a synchrotron source.

Figure 11 X-ray emission excited by an X-ray beam passing through one of the diamond anvils can pass out through the side of the other diamond anvil to be analyzed. Using a diamond with a laser-drilled hole for one anvil and a diamond with a thin-walled recess for the other greatly reduces absorption to permit high-pressure–temperature studies down to energies of 4 keV and less.

have opened the way for these techniques to be applied to investigations of a wide variety of low-energy events at HPT conditions. IXS comprises several techniques which yield different types of information. They are X-ray inelastic near-edge spectroscopy (XINES), electronic inelastic X-ray scattering (EIXS), resonant inelastic X-ray scattering (RIXS), nuclear resonant inelastic X-ray scattering (NRIXS), and phonon inelastic X-ray scattering (PIXS).

X-ray inelastic near-edge spectroscopy (XINES) is capable of making measurements that yield the same information as XANES on near core-electron absorption edge features. The principle is similar to that of electron energy loss spectroscopy (EELS). These techniques provide information about the nature of chemical bonding. Spectral features are particularly pronounced and the information particularly important for the very light elements. It is only since the development of XINES that such measurements can be made at HPT conditions because the low-energy X-ray and electron beams needed for XANES and EELS are completely blocked by any of the pressure vessels. Successful observations have been made on second-row elements from Li (56 eV) to O (543 eV) at HPs. This opens a wide new field of near K-edge spectroscopy of the very light elements.

Electronic inelastic X-ray scattering (EIXS), which is very similar to XINES in principle and instrumentation, can be used to investigate the drastic effect that pressure can have on the energy and dispersion of electronic bands. The IXS principle makes it possible to use a 10 keV X-ray beam for excitation and a monochromator capable of 0.3–1 eV resolution to probe high-energy electronic phenomena, including electronic band structure, Fermi surface, excitons, plasmons, and their dispersions at HP.

In resonant inelastic X-ray spectroscopy (RIXS) experiments, both incident and scattered X-ray energies need to be scanned. Of particular interest is the investigation of phase transitions driven by electron correlation effects that occur in transition elements and rare-earth elements and their compounds at HPs.

Nuclear resonant inelastic X-ray scattering (NRIXS) utilizes inelastic scattering to collect nuclear resonance or Mössbauer spectra. An APD directly downstream of the sample collects nuclear resonant forward scattering (NRFS) spectra which provide a precise determination of the hyperfine interaction parameter and Lamb–Mössbauer factor. APDs surrounding the sample collect NRIXS spectra. Isotopes that exhibit a nuclear resonant Mössbauer effect, for example ^{57}Fe , offer an extraordinary opportunity to make phonon DOS measurements on samples containing them, measurements that provide valuable information on dynamic, thermodynamic, and elastic properties.

PIXS requires detecting a very weak sample signal in the presence of a very strong background signal, especially when a HP vessel contains the sample. New novel HRMs which are being developed will improve the feasibility of making nonresonant PIXS measurements at HP. Such measurements would be a valuable source of information on phonon dynamics in highly compressed materials, information important for understanding vibrational thermodynamic properties, elasticity, and phase transition mechanisms.

Electrical resistance has been measured on samples as a function of pressure and at high temperature in DACs. For these experiments, fine electric leads are connected to the sample and four-lead systems have been employed for the most quantitative

measurements. A particularly novel approach, dubbed designer diamonds, has employed diamonds in which the leads are imbedded in the anvils by vapor depositing single-crystal diamond over the leads.

Magnetic measurements have been made in DACs constructed of nonmagnetic materials such as beryllium–copper. Coils for generating and picking up signals are placed as close to the sample as possible.

Sound velocity measurements have been made by three important methods, Brillouin scattering, impulse stimulated scattering, and interferometry of GHz acoustic signals. The first two of these use interactions between photons and phonons while the third generates GHz sound by a transducer and uses interferometry of the acoustic signals to measure travel time in a crystal only ~ 0.1 mm across. Sound velocities are then calculated.

Gamma rays emitted by a radioactive sample in a DAC have been counted and the effect of pressure on the decay rate measured. Pressure has been shown to increase the decay rate of the electron-capture process of ^7Be in a beryllium oxide sample.

Recent Advances

Gasketless Sample Mounting

The earliest samples subjected to pressure between two diamond anvils were not gasketed as described in Bassett (2009). A solid sample would form its own gasket as it extruded from between the anvil faces leading to a pressure gradient from highest in the center to lowest at the edges. There are a number of experiments that can take advantage of such a pressure gradient, especially when there is reason to observe all of the HP phases simultaneously. The initial pressure distribution is roughly Gaussian but changes shape as force on the anvils is cycled. Such a sample also typically has a deviatoric elastic strain resulting from the uniaxial stress. The elastic strain can be calculated from the ellipticity of diffraction rings produced by a monochromatic X-ray beam traveling perpendicular to the uniaxial force. Strength of the sample as a function of pressure can be calculated from the largest observed ellipticity as pressure is increased as described by Bassett (2006).

A gasketless DAC with a laser-drilled recess in one of the anvils (Figure 12) is described by Chou *et al.* (2008). Such a configuration has some very important advantages. When a sample is placed in the recess and sealed there by pressing the otherwise flat anvil faces together, a fluid sample can be contained to pressures of several GPa. It differs from gasketed sample mounting in several important and beneficial ways. It preserves sample volume that undergoes negligible change during most experiments. Because volume is a thermodynamic parameter, isochoric observations can have advantages similar to those of isobaric or isothermal. Needless to say, the only pressure in a sample contained in a constant volume is that resulting from increased temperature and depends on the equations of state of the phases present in the sample. However, if the isochoric behavior of the dominant component is well characterized as in the case with H_2O in aqueous samples, the observed phases of H_2O , especially liquid and vapor, can provide a reliable method for determining pressure when temperature is measured. For some compositions it can pay to load the sample in the solid state and then take advantage of the ΔP of phase transitions with increased temperature to yield even higher pressures than possible with EoS alone. The gasketless approach also has the important advantage of containing the sample in a single-composition cavity, i.e., diamond which is a relatively inert material and one that is unavoidable in most diamond anvil cell research. Although reactions between samples and diamond have been observed, they generally present less of a complication than do reactions with a metal. All of the analytical methods used for gasketed samples can also be used with gasketless samples.

Figure 12 A sample can be placed in a laser-drilled recess in one of the anvil faces and sealed there by pressing the anvil faces together. If the anvil faces have a perfectly flat polish and they are pushed together with sufficient force, a fluid can be contained to pressures of several GPa. See Chou *et al.* (2008).

Polycrystalline Diamond Anvils

Polycrystalline diamond has some very important benefits that make it desirable for use as anvils. It is tougher than single-crystal diamond which can break along cleavage directions when subjected to directed stresses which are impossible to avoid in anvils. Because of these properties, polycrystalline diamond anvils have been used to dramatically extend the pressure range of DACs as described below.

While single-crystal anvils can be desirable for diffraction studies of polycrystalline samples, polycrystalline anvils can be desirable for single-crystal samples and especially for some spectroscopic analyses in which diffraction can cause interference as described below.

Early attempts to produce polycrystalline anvils resulted in opaque anvils but subsequently, routes to forming transparent nano-polycrystalline diamond (NPD) anvils were developed (Irfune *et al.*, 2003; Sumiya and Harano, 2012). Transparency has played a key role in the history of DACs because of the need for good alignment and because so many pressure-induced changes are visible.

The Push to Ever Higher Pressures

The pressures that can be achieved with DACs have increased dramatically over the years. In the early days of DAC research pressure was measured in bars, and most DAC results were reported in the kilobar (Kbar) range. More recently, researchers have reported pressure in pascals and most DAC results are reported in gigapascals (GPa). But understandably, achieving sustained pressures over a megabar (Mbar), 100 GPa, took on a life of its own. Even after pressures reported in the literature were switched to GPa, the term megabar continued to be used when talking about higher pressures as a destination. Mao and Bell (1976) succeeded in passing the megabar goal by taking advantage of the properties of stainless steel gaskets and beveled anvils to distribute stress so as to preserve the diamond anvils to higher pressures.

A more recent important advance has been the two-stage diamond anvil cell described by Dubrovinsky *et al.* (2012). Spherical and hemispherical nanocrystalline diamond (NCD) anvils 20–50 μm in diameter have been synthesized from glassy carbon balls in a multi-anvil press also described by Dubrovinsky *et al.* (2012). These have been used as second-stage anvils using a conventional DAC for the first stage. In the two-stage cell shown in Figure 13 the hemispherical NCD anvils are placed inside of a gasketed chamber squeezed between the 300 μm anvil faces of a conventional DAC. A shallow recess in one of the 300 μm anvil faces prevents sideways slippage. The medium, paraffin or solid neon, contained in the gasket provides support to the secondary anvils while force is transferred directly to the secondary anvils by direct contact with the primary anvils. The HP medium surrounding the secondary anvils plays an important role in providing support for achieving extremely HP between the secondary anvils. In a recent paper Sakai *et al.* (2015) describe a clever way to prepare beveled secondary polycrystalline anvils with 3 μm faces from a single block so that they remain in perfect alignment without the need for a recess in one of the primary anvils.

The portion of sample that is at the maximum pressure in both designs described above is very small, and obtaining diffraction data on it is possible only with the extremely small focused X-ray beams now available at synchrotron sources. On the basis of diffraction patterns of rhenium and gold obtained at these very HPs, Dubrovinsky *et al.* (2012) report achieving sample pressures in excess of 600 GPa. Now, teragapascal (TPa) takes on significance as a new destination that once belonged to the term megabar.

Although dynamic (shockwave) pressure studies yield pressures greater than those produced by DACs, data must be collected in fractions of a second at elevated temperatures due to heating caused by compression. On the other hand, DACs offer sustained pressure at any sustained temperature. Rather than being competitors, the two methods often complement each other and provide new insights.

Figure 13 Two-stage diamond anvil cell capable of pressure in excess of 5 Mbar (500 GPa). The secondary anvils are made of polycrystalline diamond. Modified from Figure 2 in Dubrovinsky *et al.* (2012).

Diffraction Peaks in X-ray Absorption Spectra

Unfortunately, strong attenuation of some wavelengths in a spectrum can occur due to Bragg diffraction as the X-rays pass through single-crystal diamond anvils leading to unwanted sharp peaks called glitches by *Ishimatsu et al. (2012)*. There are presently two ways of dealing with this form of interference. One way is to shift the wavelengths of these unwanted peaks by changing the orientation of the DAC slightly, obtaining spectra at these different orientations, and then combining the spectra to reject the sharp peaks resulting from Bragg diffraction. The other way is to use the new polycrystalline NPD anvils described above to smooth the attenuation due to diffraction. The orientations of the crystallites in these anvils are so random that the smoothed attenuation can be considered little more than background. If a correction for the attenuation is warranted, it is easily applied. Details of this application of NPD anvils are given by *Ishimatsu et al. (2012)*. In some neutron diffraction studies in which single-crystal phases are observed polycrystalline diamond anvils can serve the same purpose.

Conclusion

Diamond anvil cells combined with many analytical techniques (**Figure 14**) have been a valuable source of information on fundamental properties of materials since the late 1950s. Improvements in diamond anvil cell designs are leading to ever higher and more accurate sustained pressures and temperatures that make it possible to utilize the improvements in analytical methods for probing ever smaller samples. These improvements, in turn, open the way to better understanding of matter at extreme conditions, providing data for understanding planetary interiors, contributing to the search for superhard materials, aiding in understanding of

Figure 14 Virtually all diamond anvil cell experiments begin with visual observation. As advances are made in miniaturization of samples that instruments are capable of analyzing, diamond anvil cells are capable of providing ever higher pressures applied to those samples by reducing a in $P = f/a$.

hydrothermal reactions that play important roles in geological processes, shedding light on biological processes including properties of macromolecules and even organisms themselves. Future research with DACs is certain to yield important new results in all of the scientific disciplines.

Bogoliubov quasiparticle, 1:134
Bogoliubov transformation, 3:126
Bohr magneton, 4:231
Bohr model of atoms, 2:40
Bohr–Sommerfeld model, 2:41, 2:653
Bohr–van Leeuwen theorem, 2:36, 2:39–40, 2:42, 2:71
Boltzmann constant, 3:3, 3:209, 4:208, 4:230
Boltzmann distribution, 2:460, 4:571, 4:572f
Boltzmann equation, 1:594–595, 4:375
Boltzmann factor, 5:169
Boltzmann statistics, 2:71
Bonding states, 3:331
Bond orientational order (BOO), 5:278
Bone, 4:739
cancellous, 4:739
cortical, 4:739
defects, 4:739–740
mineral, 4:739
Bone mineral density (BMD), 3:841
Bone repair, scaffolds for, 4:741–743
bioactive ceramic scaffolds, 4:742–743
bioactive glass scaffolds, 4:743, 4:744f
criteria for ideal scaffold, 4:741–742
polymer scaffolds, 4:742
Boolean equations, 3:555
Boolean rule, 4:688
Boric oxide anomaly, 3:183
Born approximation, 1:597
Born model, 5:208
Born–Oppenheimer approximation, 1:868, 3:503, 4:544
Boron fibers, 5:337
Bose distribution function, 2:59
Bose–Einstein condensation (BEC), 1:158–159, 1:188–189, 1:213, 1:641, 2:423–424, 2:655, 3:3, 3:10, 3:68–70, 3:74f, 3:76–77f, 3:124, 3:135–136, 3:644, 3:720–722, 5:125
coherence and superfluidity, 3:75–78
collision-induced loss, 3:646–647
in dilute atomic gases, 3:70–71
disorder, 3:79
excitonic Lyman spectroscopy, 3:647, 3:648f
excitons in cuprous oxide, 3:644–645
experiments at sub-Kelvin temperatures, 3:648–650, 3:649–650f
Fermi gases, 3:73–75
long-range interactions, 3:81
low-dimensional physics, 3:81
new macroscopic quantum state, imaging, 3:71–72
optical lattices, 3:79
quantum mixtures of ultracold atomic gases, 3:78–79
role of interactions, 3:72–73
supersolidity, 3:81–82
in 3-D ideal Bose particle system, 3:645–646
typical LO-phonon-assisted luminescence spectra, 3:645f, 3:647f
visualization of, 3:651f
Bose–Einstein condensed cold atoms, hopping amplitude of, 1:976–977, 1:976f
Bose–Einstein distribution, 5:169, 5:169f
Bose–Einstein statistics, 1:485
Bose–Fermi mixtures, 1:507, 1:512
Bose gases
dipolar, 3:132f

- noninteracting, 3:125–126
 unitary, 3:129f
 Bose–Hubbard model, 1:976–977
 Boson collisions, 1:404–405, 1:404f
 Bosonization, 1:52–62
 anomalies and duality, 1:59–62
 in 2+1 dimensions, 1:119–125
 of Dirac theory in 2+1 dimensions, 1:120–124
 of Fermi surface, 1:124–125
 Boson peak, 5:299–301
 Bosons, 1:279, 1:485, 1:487, 1:946, 1:952–953
 Bottom electrode (BE), 3:571
 Bouchaud’s trap model, 2:381
 Boundary conditions
 at metal–metal interface, 4:376–377
 metal optics, 4:371, 4:373, 4:376
 Boundary layers (heterogeneous doping), 3:153–156
 Bound states, probability densities of, 2:348f
 Bound water, 4:704
 Bragg diffraction, 4:400–401, 4:404, 5:93
 Bragg gratings, 3:778
 Bragg’s law, 4:400
 Braid group, 1:65–66, 1:72, 1:395–396, 1:397f, 1:489–492, 1:490f
 Braiding
 anyons and anyon systems via, 1:274–275
 non-Abelian anyons via, 1:272
 non-degeneracy, 1:274
 structure on fusion category, 1:277
 universality, 1:273–274
 Braids and knots, 1:269–270
 Brass, 5:614–617
 Bravais classes, 5:65–66, 5:65t, 5:66f
 Bravais lattice, 1:684, 5:71t

 Zehner exchange, 2:75
 Zener's double-exchange mechanism, 2:96
 Zero-bias anomaly, 1:901f
 Zero-dimensional systems, 3:336
 Zero-energy bound states, 2:347
 Zero group velocity, 1:776–777
 Z_2 gauge theory, 1:50–52
 Zigzag edge states, graphene, 2:355
 Zigzag nanoribbons, 2:282–284
 Z_2 index, 1:690–695
 Zirconium copper, 5:612
 Zn–Sc icosahedral quasicrystal
 phason diffuse scattering, 5:330–331, 5:331f
 structure determination, 5:328–329, 5:329f
 Zone melting in crucibles, 5:198–199
 Z_2 topological index, 1:625

Encyclopedia of Condensed Matter Physics

Second Edition

EDITOR-IN-CHIEF:

Tapash Chakraborty

University of Manitoba, Winnipeg, Manitoba, Canada

SECTION EDITORS:

Ana M. Sanchez

Department of Physics, University of Warwick, Coventry, United Kingdom

Hideo Aoki

Department of Physics, University of Tokyo, Tokyo, Japan

Robert H. Blick

Center for Hybrid Nanostructures, University of Hamburg & DESY, Hamburg, Germany

Roberto Raimondi

Mathematics and Physics Department, Roma Tre University, Rome, Italy

Rudolf A. Roemer

Department of Physics, University of Warwick, Coventry, United Kingdom

Vladimir Mihajlovic Fomin

Leibniz Institute for Solid State and Materials Research (IFW), Dresden, Germany
